Active Directory-integrated DNS servers contain the service location records (SRV) for the domain LDAP and domain controller servers. If the SVM cannot find the Active Directory LDAP servers and domain controllers, NFS or SMB server setup fails.

SVMs use the hosts name services ns-switch database to determine which name services to use and in which order when looking up information about hosts. The two supported name services for the hosts database are files and dns.

You must ensure that dns is one of the sources before you create the SMB server.

To view the statistics for DNS name services for the mgwd process and SecD process, use the Statistics UI.

#### Steps

- Determine what the current configuration is for the hosts name services database.

In this example, the hosts name service database uses the default settings.

```
vserver services name-service ns-switch show -vserver vs1 -database hosts
```

```
Vserver: vs1
Name Service Switch Database: hosts
Name Service Source Order: files, dns
```

2. Perform the following actions, if required.

- Add the DNS name service to the hosts name service database in the desired order, or reorder the sources.

In this example, the hosts database is configured to use DNS and local files in that order.

```
vserver services name-service ns-switch modify -vserver vs1 -database hosts
-sources dns,files
```

- Verify that the name services configuration is correct.

```
vserver services name-service ns-switch show -vserver vs1 -database hosts
```

3. Configure DNS services.

```
vserver services name-service dns create -vserver vs1 -domains
example.com,example2.com -name-servers 10.0.0.50,10.0.0.51
```

The vserver services name-service dns create command performs an automatic configuration validation and reports an error message if ONTAP is unable to contact the name server.

4. Verify that the DNS configuration is correct and that the service is enabled.

```
Vserver: vs1
Domains: example.com, example2.com Name
Servers: 10.0.0.50, 10.0.0.51
Enable/Disable DNS: enabled Timeout (secs): 2
Maximum Attempts: 1
```

5. Validate the status of the name servers.

```
vserver services name-service dns check -vserver vs1
```

| Vserver | Name | Server    | Status | Status Details          |
|---------|------|-----------|--------|-------------------------|
| vs1     |      | 10.0.0.50 | up     | Response time (msec): 2 |
| vs1     |      | 10.0.0.51 | up     | Response time (msec): 2 |

## Configure dynamic DNS on the SVM

If you want the Active Directory-integrated DNS server to dynamically register the DNS records of an NFS or SMB server in DNS, you must configure dynamic DNS (DDNS) on the SVM.

### Before you begin

DNS name services must be configured on the SVM. If you are using secure DDNS, you must use Active Directory-integrated DNS name servers and you must have created either an NFS or SMB server or an Active Directory account for the SVM.

### About this task

The specified fully qualified domain name (FQDN) must be unique:

- For NFS, the value specified in `-vserver-fqdn` as part of the `vserver services name-service dns dynamic-update` command becomes the registered FQDN for the LIFs.
- For SMB, the values specified as the CIFS server NetBIOS name and the CIFS server fully qualified domain name become the registered FQDN for the LIFs. This is not configurable in ONTAP. In the following scenario, the LIF FQDN is "CIFS\_VS1.EXAMPLE.COM":

```
cluster1::> cifs server show -vserver vs1

 Vserver: vs1
 CIFS Server NetBIOS Name: CIFS_VS1
 NetBIOS Domain/Workgroup Name: EXAMPLE
 Fully Qualified Domain Name: EXAMPLE.COM
 Organizational Unit: CN=Computers
 Default Site Used by LIFs Without Site Membership:
 Workgroup Name: -
 Kerberos Realm: -
 Authentication Style: domain
 CIFS Server Administrative Status: up
 CIFS Server Description:
 List of NetBIOS Aliases: -
```

 To avoid a configuration failure of an SVM FQDN that is not compliant to RFC rules for DDNS updates, use an FQDN name that is RFC compliant. For more information, see [RFC 1123](#).

### Steps

1. Configure DDNS on the SVM:

```
vserver services name-service dns dynamic-update modify -vserver vserver_name
-is- enabled true [-use-secure {true|false} -vserver-fqdn
FQDN_used_for_DNS_updates]
```

```
vserver services name-service dns dynamic-update modify -vserver vs1 -is
-enabled true - use-secure true -vserver-fqdn vs1.example.com
```

Asterisks cannot be used as part of the customized FQDN. For example, \*.netapp.com is not valid.

## 2. Verify that the DDNS configuration is correct:

```
vserver services name-service dns dynamic-update show
```

| Vserver | Is-Enabled | Use-Secure | Vserver | FQDN            | TTL |
|---------|------------|------------|---------|-----------------|-----|
| vs1     | true       | true       |         | vs1.example.com | 24h |

### Configure dynamic DNS services

If you want the Active Directory-integrated DNS server to dynamically register the DNS records of an NFS or SMB server in DNS, you must configure dynamic DNS (DDNS) on the SVM.

#### Before you begin

DNS name services must be configured on the SVM. If you are using secure DDNS, you must use Active Directory-integrated DNS name servers and you must have created either an NFS or SMB server or an Active Directory account for the SVM.

#### About this task

The specified FQDN must be unique.

To avoid a configuration failure of an SVM FQDN that is not compliant to RFC rules for DDNS updates, use an FQDN name that is RFC compliant.

#### Steps

##### 1. Configure DDNS on the SVM:

```
vserver services name-service dns dynamic-update modify -vserver vserver_name
-is- enabled true [-use-secure {true|false} -vserver-fqdn
FQDN_used_for_DNS_updates]
```

```
vserver services name-service dns dynamic-update modify -vserver vs1 -is
-enabled true - use-secure true -vserver-fqdn vs1.example.com
```

Asterisks cannot be used as part of the customized FQDN. For example, \*.netapp.com is not valid.

##### 2. Verify that the DDNS configuration is correct:

```
vserver services name-service dns dynamic-update show
```

| Vserver | Is-Enabled | Use-Secure | Vserver | FQDN            | TTL |
|---------|------------|------------|---------|-----------------|-----|
| vs1     | true       | true       |         | vs1.example.com | 24h |

# Manage your network with the CLI

## Network management overview

You can use the following information to perform basic storage network administration. You can configure physical and virtual network ports (VLANs and interface groups), create LIFs using IPv4 and IPv6, manage routing and host-resolution services in clusters, use load balancing to optimize network traffic, and monitor a cluster using SNMP.

Unless otherwise stated, these procedures apply to all versions of ONTAP 9.

You should use these procedures under the following circumstances:

- You want to understand the range of ONTAP network management capabilities.
- You want to use the CLI, not System Manager.

## Upgrade considerations

### Network features by release

Analyze the impact of network features available with each ONTAP 9 release.

| Available beginning | Feature                   | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
|---------------------|---------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| ONTAP 9.13.1        | Increased data LIF limits | <p>ONTAP provides greater flexibility by increasing data LIF scaling limits for both HA pairs and clusters.</p> <p>To view the number of IP data LIFs capable of being configured on each node, run the <code>network interface capacity details show</code> command.</p> <p>For more information on adding LIFs, see <a href="#">Create a LIF</a>.</p> <p>To see the latest data LIF limits for your environment, see <a href="#">NetApp hardware universe</a>.</p> |
| ONTAP 9.13.1        | IPv6 cluster setup        | <p>Beginning in ONTAP 9.13.1, you can assign IPv6 addresses for management LIFs on A800 and FAS8700 platforms. For ONTAP releases earlier than 9.13.1, or for 9.13.1 and later on other platforms, you must assign IPv4 addresses for management LIFs then convert to IPv6 addresses after you complete cluster setup..</p> <p>For instructions on how to convert from IPv4 to IPv6, see <a href="#">Convert from IPv4 to IPv6</a>.</p>                              |

|              |                                        |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |

| ONTAP 9.10.1 | NFS over RDMA      | <p>ONTAP offers support for NFS over RDMA, a higher performance realization of NFSv4.0 for customers with the NVIDIA GDX ecosystem. Utilizing RDMA adapters allows memory to be copied directly from storage to the GPU, circumventing the CPU overhead.</p> <p><a href="#">NFS over RDMA</a></p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| ONTAP 9.9.1  | Cluster resiliency | <p>The following cluster resiliency and diagnostic improvements improve the customer experience:</p> <ul style="list-style-type: none"> <li>• Port monitoring and avoidance: <ul style="list-style-type: none"> <li>◦ In two-node switchless cluster configurations, the system avoids ports that experience total packet loss (connectivity loss). Previously this functionality was only available in switched configurations.</li> </ul> </li> <li>• Automatic node failover: <ul style="list-style-type: none"> <li>◦ If a node cannot serve data across its cluster network, that node should not own any disks. Instead its HA partner should take over, if the partner is healthy.</li> </ul> </li> <li>• Commands to analyze connectivity issues: <ul style="list-style-type: none"> <li>◦ Use the following command to display which cluster paths are experiencing packet loss:<br/> <code>network interface check cluster-connectivity show</code> </li> </ul> </li> </ul> |

|             |                      |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
|-------------|----------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| ONTAP 9.9.1 | VIP LIF enhancements | <p>The following fields have been added to extend virtual IP (VIP) border gateway protocol (BGP) functionality:</p> <ul style="list-style-type: none"> <li>• -asn or -peer-asn (4-byte value)<br/>The attribute itself is not new, but it now uses a 4-byte integer.</li> <li>• -med</li> <li>• -use-peer-as-next-hop</li> </ul> <p>The <code>asn_integer</code> parameter specifies the autonomous system number (ASN) or peer ASN.</p> <ul style="list-style-type: none"> <li>• Beginning with ONTAP 9.8, ASN for BGP supports a 2-byte non-negative integer. This is a 16-bit number (0 - 64511 available values).</li> <li>• Beginning with ONTAP 9.9.1, ASN for BGP supports a 4-byte non-negative integer (65536 - 4294967295). The default ASN is 65501. ASN 23456 is reserved for ONTAP session establishment with peers that do not announce 4-byte ASN capability.</li> </ul> <p>You can make advanced route selections with Multi-Exit Discriminator (MED) support for path prioritization. MED is an optional attribute in the BGP update message that tells routers to select the best route for the traffic. The MED is an unsigned 32-bit integer (0 - 4294967295); lower values are preferred.</p> <p>VIP BGP provides default route automation using BGP peer grouping to simplify configuration. ONTAP has a simple way to learn default routes using the BGP peers as next-hop routers when the BGP peer is on the same subnet. To use the feature, set the <code>-use-peer-as-next-hop</code> attribute to <code>true</code>. By default, this attribute is <code>false</code>.</p> <p><a href="#">Configure virtual IP (VIP) LIFs</a></p> |

| ONTAP 9.8 | Auto port placement                                     | <p>ONTAP can automatically configure broadcast domains, select ports, and help configure network interfaces (LIFs), virtual LANs (VLANs), and link aggregation groups (LAGs) based on reachability and network topology detection.</p> <p>When you first create a cluster, ONTAP automatically discovers the networks connected to ports and configures the needed broadcast domains based on layer 2 reachability. You no longer have to configure broadcast domains manually.</p> <p>A new cluster will continue to be created with two IPspaces:</p> <p><b>Cluster IPspace:</b> Containing one broadcast domain for the cluster interconnect. You should never touch this configuration.</p> <p><b>Default IPspace:</b> Containing one or more broadcast domains for the remaining ports. Depending on your network topology, ONTAP configures additional broadcast domains as needed: Default-1, Default-2, and so on. You can rename these broadcast domains if desired, but do not modify which ports are configured in these broadcast domains.</p> <p>When you configure network interfaces, the home port selection is optional. If you do not manually select a home port, ONTAP will attempt to assign an appropriate home port in the same broadcast domain as other network interfaces in the same subnet.</p> <p>When creating a VLAN or adding the first port to a newly created LAG, ONTAP will attempt to automatically assign the VLAN or LAG to the appropriate broadcast domain based on its layer 2 reachability.</p> <p>By automatically configuring broadcast domains and ports, ONTAP helps to ensure that clients maintain access to their data during failover to another port or node in the cluster.</p> <p>Finally, ONTAP sends EMS messages when it detects that the port reachability is incorrect and provides the "network port reachability repair" command to automatically repair common misconfigurations.</p> |
| ONTAP 9.8 | Internet Protocol security (IPsec) over wire encryption | <p>To ensure data is continuously secure and encrypted, even while in transit, ONTAP uses the IPsec protocol in transport mode. IPsec offers data encryption for all IP traffic including the NFS, iSCSI, and SMB protocols. IPsec provides the only encryption in flight option for iSCSI traffic.</p> <p>Once IPsec is configured, network traffic between the client and ONTAP is protected with preventive measures to combat replay and man-in-the-middle (MITM) attacks.</p> <p><a href="#">Configure IP security (IPsec) over wire encryption</a></p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |

|           |                            |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
|-----------|----------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| ONTAP 9.8 | Virtual IP (VIP) expansion | <p>New fields have been added to the <code>network bgp peer-group</code> command. This expansion allows you to configure two additional Border Gateway Protocol (BGP) attributes for Virtual IP (VIP).</p> <p><b>AS path prepend:</b> Other factors being equal, BGP prefers to select the route with shortest AS (autonomous system) Path. You can use the optional AS path prepend attribute to repeat an autonomous system number (ASN), which increases the length of the AS path attribute. The route update with the shortest AS path will be selected by the receiver.</p> <p><b>BGP community:</b> The BGP community attribute is a 32-bit tag that can be assigned to the route updates. Each route update can have one or more BGP community tags. The neighbors receiving the prefix can examine the community value and take actions like filtering or applying specific routing policies for redistribution.</p> |
| ONTAP 9.8 | Switch CLI simplification  | <p>To simplify switch commands, the cluster and storage switch CLIs are consolidated. The consolidated switch CLIs include Ethernet switches, FC switches, and ATTO protocol bridges.</p> <p>Instead of using separate "system cluster-switch" and "system storage-switch" commands, you now use "system switch". For the ATTO protocol bridge, instead of using "storage bridge", use "system bridge".</p> <p>Switch health monitoring has similarly expanded to monitor the storage switches as well as the cluster interconnect switch. You can view health information for the cluster interconnect under "cluster_network" in the "client_device" table. You can view health information for a storage switch under "storage_network" in the "client_device" table.</p>                                                                                                                                                  |
| ONTAP 9.8 | IPv6 variable length       | <p>The supported IPv6 variable prefix length range has increased from 64 to 1 through 127 bits. A value of bit 128 remains reserved for virtual IP (VIP).</p> <p>When upgrading, non-VIP LIF lengths other than 64 bits are blocked until the last node is updated.</p> <p>When reverting an upgrade, the revert checks any non-VIP LIFs for any prefix other than 64 bits. If found, the check blocks the revert until you delete or modify the offending LIF. VIP LIFs are not checked.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                 |

|           |                                        |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
|-----------|----------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| ONTAP 9.7 | Automatic portmap service              | <p>The portmap service maps RPC services to the ports on which they listen.</p> <p>The portmap service is always accessible in ONTAP 9.3 and earlier, is configurable in ONTAP 9.4 through ONTAP 9.6, and is managed automatically beginning with ONTAP 9.7.</p> <p><b>In ONTAP 9.3 and earlier:</b> The portmap service (<code>rpcbind</code>) is always accessible on port 111 in network configurations that rely on the built-in ONTAP firewall rather than a third-party firewall.</p> <p><b>From ONTAP 9.4 through ONTAP 9.6:</b> You can modify firewall policies to control whether the portmap service is accessible on particular LIFs.</p> <p><b>Beginning with ONTAP 9.7:</b> The portmap firewall service is eliminated. Instead, the portmap port is opened automatically for all LIFs that support the NFS service.</p> <p><a href="#">Portmap service configuration</a></p> |
| ONTAP 9.7 | Cache search                           | <p>You can cache NIS <code>netgroup.byhost</code> entries using the <code>vserver services name-service nis-domain netgroup-database</code> commands.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| ONTAP 9.6 | CUBIC                                  | <p>CUBIC is the default TCP congestion control algorithm for ONTAP hardware. CUBIC replaced the ONTAP 9.5 and earlier default TCP congestion control algorithm, NewReno.</p> <p>CUBIC addresses the problems of long, fat networks (LFNs), including high round trip times (RTTs). CUBIC detects and avoids congestion. CUBIC improves performance for most environments.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
| ONTAP 9.6 | LIF service policies replace LIF roles | <p>You can assign service policies (instead of LIF roles) to LIFs that determine the kind of traffic that is supported for the LIFs. Service policies define a collection of network services supported by a LIF. ONTAP provides a set of built-in service policies that can be associated with a LIF.</p> <p>ONTAP supports service policies beginning with ONTAP 9.5; however, service policies can only be used to configure a limited number of services. Beginning with ONTAP 9.6, LIF roles are deprecated and service policies are supported for all types of services.</p> <p><a href="#">LIFs and service policies</a></p>                                                                                                                                                                                                                                                         |
| ONTAP 9.5 | NTPv3 support                          | <p>Network Time Protocol (NTP) version 3 includes symmetric authentication using SHA-1 keys, which increases network security.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |

|           |                           |                                                                                                                                                                                                                                                                                                                                                                                                                 |
|-----------|---------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| ONTAP 9.5 | SSH login security alerts | When you log in as a Secure Shell (SSH) admin user, you can view information about previous logins, unsuccessful attempts to log in, and changes to your role and privileges since your last successful login.                                                                                                                                                                                                  |
| ONTAP 9.5 | LIF service policies      | You can create new service policies or use a built-in policy. You can assign a service policy to one or more LIFs; thereby allowing the LIF to carry traffic for a single service or a list of services.<br><br><a href="#">LIFs and service policies</a>                                                                                                                                                       |
| ONTAP 9.5 | VIP LIFs and BGP support  | A VIP data LIF is a LIF that is not part of any subnet and is reachable from all ports that host a border gateway protocol (BGP) LIF in the same IPspace. A VIP data LIF eliminates the dependency of a host on individual network interfaces.<br><br><a href="#">Create a virtual IP (VIP) data LIF</a>                                                                                                        |
| ONTAP 9.5 | Multipath routing         | Multipath routing provides load balancing by utilizing all the available routes to a destination.<br><br><a href="#">Enable multipath routing</a>                                                                                                                                                                                                                                                               |
| ONTAP 9.4 | Portmap service           | The portmap service maps remote procedure call (RPC) services to the ports on which they listen.<br><br>The portmap service is always accessible in ONTAP 9.3 and earlier. Beginning with ONTAP 9.4, the portmap service is configurable.<br><br>You can modify firewall policies to control whether the portmap service is accessible on particular LIFs.<br><br><a href="#">Portmap service configuration</a> |
| ONTAP 9.4 | SSH MFA for LDAP or NIS   | SSH multi-factor authentication (MFA) for LDAP or NIS uses a public key and nsswitch to authenticate remote users.                                                                                                                                                                                                                                                                                              |
| ONTAP 9.3 | SSH MFA                   | SSH MFA for local administrator accounts use a public key and a password to authenticate local users.                                                                                                                                                                                                                                                                                                           |
| ONTAP 9.3 | SAML authentication       | You can use Security Assertion Markup Language (SAML) authentication to configure MFA for web services such as Service Processor Infrastructure (spi), ONTAP APIs, and OnCommand System Manager.                                                                                                                                                                                                                |
| ONTAP 9.2 | SSH login attempts        | You can configure the maximum number of unsuccessful SSH login attempts to protect against brute force attacks.                                                                                                                                                                                                                                                                                                 |

|           |                                |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
|-----------|--------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| ONTAP 9.2 | Digital security certificates  | ONTAP provides enhanced support for digital certificate security with Online Certificate Status Protocol (OCSP) and pre-installed default security certificates.                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| ONTAP 9.2 | Fastpath                       | <p>As part of a networking stack update for improved performance and resiliency, fast path routing support was removed in ONTAP 9.2 and later releases because it made it difficult to identify problems with improper routing tables. Therefore, it is no longer possible to set the following option in the nodeshell, and existing fast path configurations are disabled when upgrading to ONTAP 9.2 and later:</p> <pre>ip.fastpath.enable</pre> <p><a href="#">Network traffic not sent or sent out of an unexpected interface after upgrade to 9.2 due to elimination of IP Fastpath</a></p> |
| ONTAP 9.1 | Security with SNMPv3 traphosts | <p>You can configure SNMPv3 traphosts with the User-based Security Model (USM) security. With this enhancement, SNMPv3 traps can be generated by using a predefined USM user's authentication and privacy credentials.</p> <p><a href="#">Configure traphosts to receive SNMP notifications</a></p>                                                                                                                                                                                                                                                                                                |
| ONTAP 9.0 | IPv6                           | <p>Dynamic DNS (DDNS) name service is available on IPv6 LIFs.</p> <p><a href="#">Create a LIF</a></p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| ONTAP 9.0 | LIFs per node                  | <p>The supported number of LIFs per node has increased for some systems. See the Hardware Universe for the number of LIFs supported on each platform for a specified ONTAP release.</p> <p><a href="#">Create a LIF</a></p> <p><a href="#">NetApp hardware universe</a></p>                                                                                                                                                                                                                                                                                                                        |
| ONTAP 9.0 | LIF management                 | <p>ONTAP and System Manager automatically detect and isolate network port failures. LIFs are automatically migrated from degraded ports to healthy ports.</p> <p><a href="#">Monitor the health of network ports</a></p>                                                                                                                                                                                                                                                                                                                                                                           |
| ONTAP 9.0 | LLDP                           | <p>Link Layer Discovery Protocol (LLDP) provides a vendor-neutral interface for verifying and troubleshooting cabling between an ONTAP system and a switch or router. It is an alternative to Cisco Discovery Protocol (CDP), a proprietary link layer protocol developed by Cisco Systems.</p> <p><a href="#">Enable or Disable LLDP</a></p>                                                                                                                                                                                                                                                      |

|           |                                 |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
|-----------|---------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| ONTAP 9.0 | UC compliance with DSCP marking | <p>Unified Capability (UC) compliance with Differentiated Services Code Point (DSCP) marking.</p> <p>Differentiated Services Code Point (DSCP) marking is a mechanism for classifying and managing network traffic and is a component of Unified Capability (UC) compliance. You can enable DSCP marking on outgoing (egress) IP packet traffic for a given protocol with a default or user-provided DSCP code.</p> <p>If you do not provide a DSCP value when enabling DSCP marking for a given protocol, a default is used:</p> <ul style="list-style-type: none"> <li><b>0x0A (10)</b>: The default value for data protocols/traffic.</li> <li><b>0x30 (48)</b>: The default value for control protocols/traffic.</li> </ul> <p><a href="#">DSCP marking for US compliance</a></p> |
| ONTAP 9.0 | SHA-2 password hash function    | <p>To enhance password security, ONTAP 9 supports the SHA-2 password hash function and uses SHA-512 by default for hashing newly created or changed passwords.</p> <p>Existing user accounts with unchanged passwords continue to use the MD5 hash function after the upgrade to ONTAP 9 or later, and users can continue to access their accounts. However, it is strongly recommended that you migrate MD5 accounts to SHA-512 by having users change their passwords.</p>                                                                                                                                                                                                                                                                                                          |
| ONTAP 9.0 | FIPS 140-2 support              | <p>You can enable the Federal Information Processing Standard (FIPS) 140-2 compliance mode for cluster-wide control plane web service interfaces.</p> <p>By default, the FIPS 140-2 only mode is disabled.</p> <p><a href="#">Configure network security using Federal Information Processing Standards (FIPS)</a></p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                |

### Verify your networking configuration after upgrading to ONTAP 9.8 or later

After an upgrade to ONTAP 9.8, you should verify your network configuration. After the upgrade, ONTAP automatically monitors layer 2 reachability.

Use the following command to verify each port has reachability to its expected broadcast domain:

```
network port reachability show -detail
```

The command output contains reachability results. Use the following decision tree and table to understand the reachability results (reachability-status) and determine what, if anything, to do next.

| reachability-status | Description |
|---------------------|-------------|
|---------------------|-------------|

|                            |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
|----------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| ok                         | <p>The port has layer 2 reachability to its assigned broadcast domain.</p> <p>If the reachability-status is "ok", but there are "unexpected ports", consider merging one or more broadcast domains. | multi-domain-reachability  | <p>The port has layer 2 reachability to its assigned broadcast domain; however, it also has layer 2 reachability to at least one other broadcast domain.</p> <p>Examine the physical connectivity and switch configuration to determine if it is incorrect or if the port's assigned broadcast domain needs to be merged with one or more broadcast domains.</p> <p>For more information, see <a href="#">Merge broadcast domains</a> or <a href="#">Repair port reachability</a>.</p>                                                                                                                    |
| unknown                    | <p>If the reachability-status is "unknown", then wait a few minutes and try the command again.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |

After you repair a port, you need to check for and resolve displaced LIFs and VLANs. If the port was part of an interface group, you also need to understand what happened to that interface group. For more information, see [Repair port reachability](#).

## Networking components of a cluster

## Overview

You should familiarize yourself with the networking components of a cluster before setting up the cluster. Configuring the physical networking components of a cluster into logical components provides the flexibility and multi-tenancy functionality in ONTAP.

The various networking components in a cluster are as follows:

- Physical ports

Network interface cards (NICs) and host bus adapters (HBAs) provide physical (Ethernet and Fibre Channel) connections from each node to the physical networks (management and data networks).

For site requirements, switch information, port cabling information, and controller onboard port cabling, see the Hardware Universe at [hwu.netapp.com](http://hwu.netapp.com).

- Logical ports

Virtual local area networks (VLANs) and interface groups constitute the logical ports. Interface groups treat several physical ports as a single port, while VLANs subdivide a physical port into multiple separate ports.

- IPspaces

You can use an IPspace to create a distinct IP address space for each SVM in a cluster. Doing so enables clients in administratively separate network domains to access cluster data while using overlapping IP addresses from the same IP address subnet range.

- Broadcast domains

A broadcast domain resides in an IPspace and contains a group of network ports, potentially from many nodes in the cluster, that belong to the same layer 2 network. The ports in the group are used in an SVM for data traffic.

- Subnets

A subnet is created within a broadcast domain and contains a pool of IP addresses that belong to the same layer 3 subnet. This pool of IP addresses simplifies IP address allocation during LIF creation.

- Logical interfaces

A logical interface (LIF) is an IP address or a worldwide port name (WWPN) that is associated with a port. It is associated with attributes such as failover groups, failover rules, and firewall rules. A LIF communicates over the network through the port (physical or logical) to which it is currently bound.

The different types of LIFs in a cluster are data LIFs, cluster-scoped management LIFs, node-scoped management LIFs, intercluster LIFs, and cluster LIFs. The ownership of the LIFs depends on the SVM where the LIF resides. Data LIFs are owned by data SVMs, node-scoped management LIFs, cluster-scoped management, and intercluster LIFs are owned by the admin SVMs, and cluster LIFs are owned by the cluster SVM.

- DNS zones

DNS zone can be specified during the LIF creation, providing a name for the LIF to be exported through the cluster's DNS server. Multiple LIFs can share the same name, allowing the DNS load balancing feature to distribute IP addresses for the name according to load.

SVMs can have multiple DNS zones.

- Routing

Each SVM is self-sufficient with respect to networking. An SVM owns LIFs and routes that can reach each of the configured external servers.

The following figure illustrates how the different networking components are associated in a four-node cluster:

### Network cabling guidelines

Network cabling best practices separate traffic into the following networks: cluster, management, and data.

You should cable a cluster so that the cluster traffic is on a separate network from all other traffic. It is an optional, but recommended practice to have network management traffic separated from data and intracluster traffic. By maintaining separate networks, you can achieve better performance, ease of administration, and improved security and management access to the nodes.

The following diagram illustrates the network cabling of a four-node HA cluster that includes three separate networks:

You should follow certain guidelines when cabling network connections:

- Each node should be connected to three distinct networks.

One network is for management, one is for data access, and one is for intracenter communication. The management and data networks can be logically separated.

- You can have more than one data network connection to each node for improving the client (data) traffic flow.
- A cluster can be created without data network connections, but it must include a cluster interconnect connection.
- There should always be two or more cluster connections to each node, but nodes on FAS22xx systems can be configured with a single 10-GbE cluster port.

For more information on network cabling, see the [AFF and FAS System Documentation Center](#) and the [Hardware Universe](#).

## **Relationship between broadcast domains, failover groups, and failover policies**

Broadcast domains, failover groups, and failover policies work together to determine which port will take over when the node or port on which a LIF is configured fails.

A broadcast domain lists all the ports reachable in the same layer 2 Ethernet network. An Ethernet broadcast packet sent from one of the ports is seen by all other ports in the broadcast domain. This common-reachability characteristic of a broadcast domain is important to LIFs because if a LIF were to fail over to any other port in the broadcast domain, it could still reach every local and remote host that was reachable from the original port.

Failover groups define the ports within a broadcast domain that provide LIF failover coverage for each other. Each broadcast domain has one failover group that includes all its ports. This failover group containing all ports in the broadcast domain is the default and recommended failover group for the LIF. You can create failover groups with smaller subsets that you define, such as a failover group of ports that have the same link speed within a broadcast domain.

A failover policy dictates how a LIF uses the ports of a failover group when a node or port goes down. Consider the failover policy as a type of filter that is applied to a failover group. The failover targets for a LIF (the set of ports to which a LIF can failover) is determined by applying the LIF's failover policy to the LIF's failover group in the broadcast domain.

You can view the failover targets for a LIF using the following CLI command:

```
network interface show -failover
```

NetApp strongly recommends using the default failover policy for your LIF type.

### **Decide which LIF failover policy to use**

Decide whether to use the recommended, default failover policy or whether to change it based on your LIF type and environment.

### **Failover policy decision tree**

### Default failover policies by LIF type

| LIF type         | Default failover policy | Description                                                                                 |
|------------------|-------------------------|---------------------------------------------------------------------------------------------|
| BGP LIFs         | disabled                | LIF does not fail over to another port.                                                     |
| Cluster LIFs     | local-only              | LIF fails over to ports on the same node only.                                              |
| Cluster-mgmt LIF | broadcast-domain-wide   | LIF fails over to ports in the same broadcast domain, on any and every node in the cluster. |

|                      |                |                                                              |
|----------------------|----------------|--------------------------------------------------------------|
| Intercluster LIFs    | local-only     | LIF fails over to ports on the same node only.               |
| NAS data LIFs        | system-defined | LIF fails over to one other node that is not the HA partner. |
| Node management LIFs | local-only     | LIF fails over to ports on the same node only.               |
| SAN data LIFs        | disabled       | LIF does not fail over to another port.                      |

The "sfo-partner-only" failover policy is not a default, but can be used when you want the LIF to fail over to a port on the home node or SFO partner only.

## Configure network ports (cluster administrators only)

### Overview

Ports are either physical ports (NICs) or virtualized ports, such as interface groups or VLANs.

Virtual local area networks (VLANs) and interface groups constitute the virtual ports. Interface groups treat several physical ports as a single port, while VLANs subdivide a physical port into multiple separate logical ports.

- Physical ports: LIFs can be configured directly on physical ports.
- Interface group: A port aggregate containing two or more physical ports that act as a single trunk port. An interface group can be single-mode, multimode, or dynamic multimode.
- VLAN: A logical port that receives and sends VLAN-tagged (IEEE 802.1Q standard) traffic. VLAN port characteristics include the VLAN ID for the port. The underlying physical port or interface group ports are considered VLAN trunk ports, and the connected switch ports must be configured to trunk the VLAN IDs.

The underlying physical port or interface group ports for a VLAN port can continue to host LIFs, which transmit and receive untagged traffic.

- Virtual IP (VIP) port: A logical port that is used as the home port for a VIP LIF. VIP ports are created automatically by the system and support only a limited number of operations. VIP ports are supported beginning with ONTAP 9.5.

The port naming convention is *enumeratorletter*:

- The first character describes the port type.  
"e" represents Ethernet.
- The second character indicates the numbered slot in which the port adapter is located.
- The third character indicates the port's position on a multiport adapter.  
"a" indicates the first port, "b" indicates the second port, and so on.

For example, e0b indicates that an Ethernet port is the second port on the node's motherboard.

VLANs must be named by using the syntax `port_name-vlan-id`.

`port_name` specifies the physical port or interface group.

`vlan-id` specifies the VLAN identification on the network. For example, e1c-80 is a valid VLAN name.

## Combine physical ports to create interface groups

An interface group, also known as a Link Aggregation Group (LAG), is created by combining two or more physical ports into a single logical port. The logical port provides increased resiliency, increased availability, and load sharing.

### Interface group types

Three types of interface groups are supported on the storage system: single-mode, static multimode, and dynamic multimode. Each interface group provides different levels of fault tolerance. Multimode interface groups provide methods for load balancing network traffic.

### Characteristics of single-mode interface groups

In a single-mode interface group, only one of the interfaces in the interface group is active. The other interfaces are on standby, ready to take over if the active interface fails.

Characteristics of a single-mode interface groups:

- For failover, the cluster monitors the active link and controls failover.  
Because the cluster monitors the active link, there is no switch configuration required.
- There can be more than one interface on standby in a single-mode interface group.
- If a single-mode interface group spans multiple switches, you must connect the switches with an Inter-Switch link (ISL).
- For a single-mode interface group, the switch ports must be in the same broadcast domain.
- Link-monitoring ARP packets, which have a source address of 0.0.0.0, are sent over the ports to verify that the ports are in the same broadcast domain.

The following figure is an example of a single-mode interface group. In the figure, e0a and e1a are part of the a0a single-mode interface group. If the active interface, e0a, fails, the standby e1a interface takes over and maintains the connection to the switch.

To accomplish single-mode functionality, the recommended approach is to instead use failover groups. By using a failover group, the second port can still be used for other LIFs and need not remain unused. Additionally, failover groups can span more than two ports and can span ports on multiple nodes.

## Characteristics of static multimode interface groups

The static multimode interface group implementation in ONTAP complies with IEEE 802.3ad (static). Any switch that supports aggregates, but does not have control packet exchange for configuring an aggregate, can be used with static multimode interface groups.

Static multimode interface groups do not comply with IEEE 802.3ad (dynamic), also known as Link Aggregation Control Protocol (LACP). LACP is equivalent to Port Aggregation Protocol (PAgP), the proprietary link aggregation protocol from Cisco.

The following are characteristics of a static multimode interface group:

- All interfaces in the interface group are active and share a single MAC address.
  - Multiple individual connections are distributed among the interfaces in the interface group.
  - Each connection or session uses one interface within the interface group.

When you use the sequential load balancing scheme, all sessions are distributed across available links on a packet-by-packet basis, and are not bound to a particular interface from the interface group.
- Static multimode interface groups can recover from a failure of up to "n-1" interfaces, where n is the total number of interfaces that form the interface group.
- If a port fails or is unplugged, the traffic that was traversing the failed link is automatically redistributed to one of the remaining interfaces.
- Static multimode interface groups can detect a loss of link, but they cannot detect a loss of connectivity to the client or switch misconfigurations that might impact connectivity and performance.
- A static multimode interface group requires a switch that supports link aggregation over multiple switch ports.

The switch is configured so that all ports to which links of an interface group are connected are part of a single logical port. Some switches might not support link aggregation of ports configured for jumbo frames. For more information, see your switch vendor's documentation.
- Several load balancing options are available to distribute traffic among the interfaces of a static multimode interface group.

The following figure is an example of a static multimode interface group. Interfaces e0a, e1a, e2a, and e3a are part of the a1a multimode interface group. All four interfaces in the a1a multimode interface group are active.

Several technologies exist that enable traffic in a single aggregated link to be distributed across multiple physical switches. The technologies used to enable this capability vary among networking products. Static multimode interface groups in ONTAP conform to the IEEE 802.3 standards. If a particular multiple switch link aggregation technology is said to interoperate with or conform to the IEEE 802.3 standards, it should operate with ONTAP.

The IEEE 802.3 standard states that the transmitting device in an aggregated link determines the physical interface for transmission. Therefore, ONTAP is only responsible for distributing outbound traffic, and cannot control how inbound frames arrive. If you want to manage or control the transmission of inbound traffic on an aggregated link, that transmission must be modified on the directly connected network device.

### **Dynamic multimode interface group**

Dynamic multimode interface groups implement Link Aggregation Control Protocol (LACP) to communicate group membership to the directly attached switch. LACP enables you to detect the loss of link status and the inability of the node to communicate with the direct-attached switch port.

Dynamic multimode interface group implementation in ONTAP complies with IEEE 802.3 AD (802.1 AX). ONTAP does not support Port Aggregation Protocol (PAgP), which is a proprietary link aggregation protocol from Cisco.

A dynamic multimode interface group requires a switch that supports LACP.

ONTAP implements LACP in nonconfigurable active mode that works well with switches that are configured in either active or passive mode. ONTAP implements the long and short LACP timers (for use with nonconfigurable values 3 seconds and 90 seconds), as specified in IEEE 802.3 AD (802.1AX).

The ONTAP load balancing algorithm determines the member port to be used to transmit outbound traffic, and does not control how inbound frames are received. The switch determines the member (individual physical port) of its port channel group to be used for transmission, based on the load balancing algorithm configured in the switch's port channel group. Therefore, the switch configuration determines the member port (individual physical port) of the storage system to receive traffic. For more information about configuring the switch, see the documentation from your switch vendor.

If an individual interface fails to receive successive LACP protocol packets, then that individual interface is marked as "lag\_inactive" in the output of "ifgrp status" command. Existing traffic is automatically rerouted to any remaining active interfaces.

The following rules apply when using dynamic multimode interface groups:

- Dynamic multimode interface groups should be configured to use the port-based, IP-based, MAC-based, or round robin load balancing methods.
- In a dynamic multimode interface group, all interfaces must be active and share a single MAC address.

The following figure is an example of a dynamic multimode interface group. Interfaces e0a, e1a, e2a, and e3a are part of the a1a multimode interface group. All four interfaces in the a1a dynamic multimode interface group are active.

### Load balancing in multimode interface groups

You can ensure that all interfaces of a multimode interface group are equally utilized for outgoing traffic by using the IP address, MAC address, sequential, or port-based load balancing methods to distribute network traffic equally over the network ports of a multimode interface group.

The load balancing method for a multimode interface group can be specified only when the interface group is created.

**Best Practice:** Port-based load balancing is recommended whenever possible. Use port-based load balancing unless there is a specific reason or limitation in the network that prevents it.

#### Port-based load balancing

Port-based load balancing is the recommended method.

You can equalize traffic on a multimode interface group based on the transport layer (TCP/UDP) ports by using the port-based load balancing method.

The port-based load balancing method uses a fast hashing algorithm on the source and destination IP addresses along with the transport layer port number.

#### IP address and MAC address load balancing

IP address and MAC address load balancing are the methods for equalizing traffic on multimode interface groups.

These load balancing methods use a fast hashing algorithm on the source and destination addresses (IP

address and MAC address). If the result of the hashing algorithm maps to an interface that is not in the UP link-state, the next active interface is used.

Do not select the MAC address load balancing method when creating interface groups on a system that connects directly to a router. In such a setup, for every outgoing IP frame, the destination MAC address is the MAC address of the router. As a result, only one interface of the interface group is used.

IP address load balancing works in the same way for both IPv4 and IPv6 addresses.

## Sequential load balancing

You can use sequential load balancing to equally distribute packets among multiple links using a round robin algorithm. You can use the sequential option for load balancing a single connection's traffic across multiple links to increase single connection throughput.

However, because sequential load balancing may cause out-of-order packet delivery, extremely poor performance can result. Therefore, sequential load balancing is generally not recommended.

## Create an interface group or LAG

You can create an interface group or LAG—single-mode, static multimode, or dynamic multimode (LACP)—to present a single interface to clients by combining the capabilities of the aggregated network ports.

The procedure you follow depends on the interface that you use—System Manager or the CLI:

## System Manager

### Use System Manager to create a LAG

#### Steps

1. Select **Network > Ethernet port > + Link Aggregation Group** to create a LAG.
2. Select the node from the drop-down list.
3. Choose from the following:
  - a. ONTAP to **Automatically select broadcast domain (recommended)**.
  - b. To manually select a broadcast domain.
4. Select the ports to form the LAG.
5. Select the mode:
  - a. Single: Only one port is used at a time.
  - b. Multiple: All ports can be used simultaneously.
  - c. LACP: The LACP protocol determines the ports that can be used.
6. Select the load balancing:
  - a. IP based
  - b. MAC based
  - c. Port
  - d. Sequential
7. Save your changes.

The screenshot shows the ONTAP System Manager web interface. The left sidebar has a dark blue background with white text, showing navigation links like DASHBOARD, INSIGHTS, STORAGE, NETWORK (which is currently selected), and PROTECTION. The main content area has a light gray background. A modal window titled "Add Link Aggregation Group" is open. Inside the modal, there are several configuration fields:

- NODE:** A dropdown menu set to "sti47-vsim-ucs521".
- BROADCAST DOMAIN:** A dropdown menu set to "Automatically select broadcast domain (Recommended)". A red note to the right of this field says: "Note: Instead of a global switch or checkbox, what if we expose BD dropdown with 'Automatic' as a default selection?"
- PORTS TO INCLUDE:** Two checkboxes for ports "e0c" and "e0f", both of which are unchecked.
- MODE:** A radio button group with three options: "Single" (selected), "Multiple", and "LACP". The "Single" option is described as "Only one port is used at a time".
- LOAD DISTRIBUTION:** A radio button group with two options: "IP based" (selected) and "MAC based". The "IP based" option is described as "Network traffic is distributed based on the destination IP address".

## CLI

### Use the CLI to create an interface group

For a complete list of configuration restrictions that apply to port interface groups, see the `network port ifgrp add-port` man page.

When creating a multimode interface group, you can specify any of the following load-balancing methods:

- `port`: Network traffic is distributed on the basis of the transport layer (TCP/UDP) ports. This is the recommended load-balancing method.
- `mac`: Network traffic is distributed on the basis of MAC addresses.
- `ip`: Network traffic is distributed on the basis of IP addresses.
- `sequential`: Network traffic is distributed as it is received.

The MAC address of an interface group is determined by the order of the underlying ports and how these ports initialize during bootup. You should therefore not assume that the ifgrp MAC address is persistent across reboots or ONTAP upgrades.

## Step

Use the `network port ifgrp create` command to create an interface group.

Interface groups must be named using the syntax `a<number><letter>`. For example, `a0a`, `a0b`, `a1c`, and `a2a` are valid interface group names.

For more information about this command, see [ONTAP 9 commands](#).

The following example shows how to create an interface group named `a0a` with a distribution function of `port` and a mode of `multimode`:

```
network port ifgrp create -node cluster-1-01 -ifgrp a0a -distr-func port -mode multimode
```

## Add a port to an interface group or LAG

You can add up to 16 physical ports to an interface group or LAG for all port speeds.

The procedure you follow depends on the interface that you use—System Manager or the CLI:

## **System Manager**

### **Use System Manager to add a port to a LAG**

#### **Steps**

1. Select **Network > Ethernet port > LAG** to edit a LAG.
2. Select additional ports on the same node to add to the LAG.
3. Save your changes.

#### **CLI**

### **Use the CLI to add ports to an interface group**

#### **Step**

Add network ports to the interface group:

```
network port ifgrp add-port
```

For more information about this command, see [ONTAP 9 commands](#).

The following example shows how to add port e0c to an interface group named a0a:

```
network port ifgrp add-port -node cluster-1-01 -ifgrp a0a -port e0c
```

Beginning with ONTAP 9.8, interface groups are automatically placed into an appropriate broadcast domain about one minute after the first physical port is added to the interface group. If you do not want ONTAP to do this, and prefer to manually place the ifgrp into a broadcast domain, then specify the **-skip-broadcast-domain-placement** parameter as part of the **ifgrp add-port** command.

## **Remove a port from an interface group or LAG**

You can remove a port from an interface group that hosts LIFs, as long as it is not the last port in the interface group. There is no requirement that the interface group must not host LIFs or that the interface group must not be the home port of a LIF considering that you are not removing the last port from the interface group. However, if you are removing the last port, then you must migrate or move the LIFs from the interface group first.

#### **About this task**

You can remove up to 16 ports (physical interfaces) from an interface group or LAG.

The procedure you follow depends on the interface that you use—System Manager or the CLI:

## **System Manager**

### **Use System Manager to remove a port from a LAG**

#### **Steps**

1. Select **Network > Ethernet port > LAG** to edit a LAG.
2. Select the ports to remove from the LAG.
3. Save your changes.

#### **CLI**

### **Use the CLI to remove ports from an interface group**

#### **Step**

Remove network ports from an interface group:

```
network port ifgrp remove-port
```

The following example shows how to remove port e0c from an interface group named a0a:

```
network port ifgrp remove-port -node cluster-1-01 -ifgrp a0a -port e0c
```

## **Delete an interface group or LAG**

You can delete interface groups or LAGs if you want to configure LIFs directly on the underlying physical ports or decide to change the interface group or LAG mode or distribution function.

#### **Before you begin**

- The interface group or LAG must not be hosting a LIF.
- The interface group or LAG must be neither the home port nor the failover target of a LIF.

The procedure you follow depends on the interface that you use—System Manager or the CLI:

## System Manager

### Use System Manager to delete a LAG

#### Steps

1. Select **Network > Ethernet port > LAG** to delete a LAG.
2. Select the LAG you want to remove.
3. Delete the LAG.

#### CLI

### Use the CLI to delete an interface group

#### Step

Use the `network port ifgrp delete` command to delete an interface group.

For more information about this command, see [ONTAP 9 commands](#).

The following example shows how to delete an interface group named `a0b`:

```
network port ifgrp delete -node cluster-1-01 -ifgrp a0b
```

## Configure VLANs over physical ports

VLANs provide logical segmentation of networks by creating separate broadcast domains that are defined on a switch port basis as opposed to the traditional broadcast domains, defined on physical boundaries.

A VLAN can span multiple physical network segments. The end-stations belonging to a VLAN are related by function or application.

For example, end-stations in a VLAN might be grouped by departments, such as engineering and accounting, or by projects, such as release1 and release2. Because physical proximity of the end-stations is not essential in a VLAN, you can disperse the end-stations geographically and still contain the broadcast domain in a switched network.

You can manage VLANs by creating, deleting, or displaying information about them.

You should not create a VLAN on a network interface with the same identifier as the native VLAN of the switch. For example, if the network interface `e0b` is on native VLAN 10, you should not create a VLAN `e0b-10` on that interface.

### Create a VLAN

You can create a VLAN for maintaining separate broadcast domains within the same network domain by using System Manager or the `network port vlan create` command.

### Before you begin

Confirm that the following requirements have been met:

- The switches deployed in the network must either comply with IEEE 802.1Q standards or have a vendor-

specific implementation of VLANs.

- For supporting multiple VLANs, an end-station must be statically configured to belong to one or more VLANs.
- The VLAN is not attached to a port hosting a cluster LIF.
- The VLAN is not attached to ports assigned to the Cluster IPspace.
- The VLAN is not created on an interface group port that contains no member ports.

### About this task

Creating a VLAN attaches the VLAN to the network port on a specified node in a cluster.

When you configure a VLAN over a port for the first time, the port might go down, resulting in a temporary disconnection of the network. Subsequent VLAN additions to the same port do not affect the port state.

You should not create a VLAN on a network interface with the same identifier as the native VLAN of the switch. For example, if the network interface e0b is on native VLAN 10, you should not create a VLAN e0b-10 on that interface.

The procedure you follow depends on the interface that you use—System Manager or the CLI:

## System Manager

### Use System Manager to create a VLAN

Beginning with ONTAP 9.12.0, you can automatically select the broadcast domain or manually select one from the list. Previously, broadcast domains were always automatically selected based on layer 2 connectivity. If you manually select a broadcast domain, a warning appears indicating that manually selecting a broadcast domain could result in loss of connectivity.

#### Steps

1. Select **Network > Ethernet port > + VLAN**.
2. Select the node from the drop-down list.
3. Choose from the following:
  - a. ONTAP to **Automatically select broadcast domain (recommended)**.
  - b. To manually select a broadcast domain from the list.
4. Select the ports to form the VLAN.
5. Specify the VLAN ID.
6. Save your changes.

## CLI

### Use the CLI to create a VLAN

In certain circumstances, if you want to create the VLAN port on a degraded port without correcting the hardware issue or any software misconfiguration, then you can set the `-ignore-health-status` parameter of the `network port modify` command as `true`.

#### Steps

1. Use the `network port vlan create` command to create a VLAN.
2. You must specify either the `vlan-name` or the `port` and `vlan-id` options when creating a VLAN. The VLAN name is a combination of the name of the port (or interface group) and the network switch VLAN identifier, with a hyphen in between. For example, `e0c-24` and `e1c-80` are valid VLAN names.

The following example shows how to create a VLAN `e1c-80` attached to network port `e1c` on the node `cluster-1-01`:

```
network port vlan create -node cluster-1-01 -vlan-name e1c-80
```

Beginning with ONTAP 9.8, VLANs are automatically placed into appropriate broadcast domains about one minute after their creation. If you do not want ONTAP to do this, and prefer to manually place the VLAN into a broadcast domain, then specify the `-skip-broadcast-domain-placement` parameter as part of the `vlan create` command.

For more information about this command, see [ONTAP 9 commands](#).

## Edit a VLAN

You can change the broadcast domain or disable a VLAN.

### Use System Manager to edit a VLAN

Beginning with ONTAP 9.12.0, you can automatically select the broadcast domain or manually select one from the list. Previously broadcast domains were always automatically selected based on layer 2 connectivity. If you manually select a broadcast domain, a warning appears indicating that manually selecting a broadcast domain could result in loss of connectivity.

#### Steps

1. Select **Network > Ethernet port > VLAN**.
2. Select the edit icon.
3. Do one of the following:
  - Change the broadcast domain by selecting a different one from the list.
  - Clear the **Enabled** check box.
4. Save your changes.

## Delete a VLAN

You might have to delete a VLAN before removing a NIC from its slot. When you delete a VLAN, it is automatically removed from all of the failover rules and groups that use it.

### Before you begin

Make sure there are no LIFs associated with the VLAN.

### About this task

Deletion of the last VLAN from a port might cause a temporary disconnection of the network from the port.

The procedure you follow depends on the interface that you use—System Manager or the CLI:

## **System Manager**

### **Use System Manager to delete a VLAN**

#### **Steps**

1. Select **Network > Ethernet port > VLAN**.
2. Select the VLAN you want to remove.
3. Click **Delete**.

#### **CLI**

### **Use the CLI to delete a VLAN**

#### **Step**

Use the `network port vlan delete` command to delete a VLAN.

The following example shows how to delete VLAN `e1c-80` from network port `e1c` on the node `cluster-1-01`:

```
network port vlan delete -node cluster-1-01 -vlan-name e1c-80
```

## **Modify network port attributes**

You can modify the autonegotiation, duplex, flow control, speed, and health settings of a physical network port.

#### **Before you begin**

The port that you want to modify must not be hosting any LIFs.

#### **About this task**

- It is not recommended to modify the administrative settings of the 100 GbE, 40 GbE, 10 GbE or 1 GbE network interfaces.

The values that you set for duplex mode and port speed are referred to as administrative settings.

Depending on network limitations, the administrative settings can differ from the operational settings (that is, the duplex mode and speed that the port actually uses).

- It is not recommended to modify the administrative settings of the underlying physical ports in an interface group.

The `-up-admin` parameter (available at the advanced privilege level) modifies the administrative settings of the port.

- It is not recommended to set the `-up-admin` administrative setting to false for all ports on a node, or for the port that hosts the last operational cluster LIF on a node.
- It is not recommended to modify the MTU size of the management port, `e0M`.
- The MTU size of a port in a broadcast domain cannot be changed from the MTU value that is set for the broadcast domain.

- The MTU size of a VLAN cannot exceed the value of the MTU size of its base port.

## Steps

1. Modify the attributes of a network port:

```
network port modify
```

2. You can set the `-ignore-health-status` field to true for specifying that the system can ignore the network port health status of a specified port.

The network port health status is automatically changed from degraded to healthy, and this port can now be used for hosting LIFs. You should set the flow control of cluster ports to `none`. By default, the flow control is set to `full`.

The following command disables the flow control on port e0b by setting the flow control to `none`:

```
network port modify -node cluster-1-01 -port e0b -flowcontrol-admin none
```

## Modify MTU setting for interface group ports

To modify the MTU setting for interface groups, you must modify the MTU of the broadcast domain.

VLAN MTU size should match the broadcast domain MTU of the underlying interface groups and physical ports. If a different VLAN setting is needed for a VLAN, it must not exceed the size specified by the underlying broadcast domain.

## Steps

1. Modify the broadcast domain settings:

```
broadcast-domain modify -broadcast-domain broadcast_domain_name -mtu
mtu_setting
```

The following warning message is displayed:

```
Warning: Changing broadcast domain settings will cause a momentary data-
serving interruption.
Do you want to continue? {y|n}: y
```

2. Enter `y` to continue.

3. Verify that the MTU setting were modified correctly:

```
network port show
```

```

network port show
(network port show)
Node: vsim-01

 Ignore
 Speed (Mbps) Health Health
Port IPspace Broadcast Domain Link MTU Admin/Oper Status Status
---- ----- ----- ----- ----- ----- ----- -----
a0a Default Default-1 up 1300 auto/1000 healthy false
e0a Default Default-1 up 1300 auto/1000 healthy false
e0b Default Default up 1500 auto/1000 healthy false
e0c Default Default up 1500 auto/1000 healthy false
e0d Default Default up 1500 auto/1000 healthy false
5 entries were displayed.

```

## Monitor the health of network ports

ONTAP management of network ports includes automatic health monitoring and a set of health monitors to help you identify network ports that might not be suitable for hosting LIFs.

### About this task

If a health monitor determines that a network port is unhealthy, it warns administrators through an EMS message or marks the port as degraded. ONTAP avoids hosting LIFs on degraded network ports if there are healthy alternative failover targets for that LIF. A port can become degraded because of a soft failure event, such as link flapping (links bouncing quickly between up and down) or network partitioning:

- Network ports in the cluster IPspace are marked as degraded when they experience link flapping or loss of layer 2 (L2) reachability to other network ports in the broadcast domain.
- Network ports in non-cluster IPspaces are marked as degraded when they experience link flapping.

You must be aware of the following behaviors of a degraded port:

- A degraded port cannot be included in a VLAN or an interface group.

If a member port of an interface group is marked as degraded, but the interface group is still marked as healthy, LIFs can be hosted on that interface group.

- LIFs are automatically migrated from degraded ports to healthy ports.
- During a failover event, a degraded port is not considered as the failover target. If no healthy ports are available, degraded ports host LIFs according to the normal failover policy.
- You cannot create, migrate, or revert a LIF to a degraded port.

You can modify the `ignore-health-status` setting of the network port to `true`. You can then host a LIF on the healthy ports.

### Steps

1. Log in to the advanced privilege mode:

```
set -privilege advanced
```

2. Check which health monitors are enabled for monitoring network port health:

```
network options port-health-monitor show
```

The health status of a port is determined by the value of health monitors.

The following health monitors are available and enabled by default in ONTAP:

- Link-flapping health monitor: Monitors link flapping

If a port has link flapping more than once in five minutes, this port is marked as degraded.

- L2 reachability health monitor: Monitors whether all ports configured in the same broadcast domain have L2 reachability to each other

This health monitor reports L2 reachability issues in all IPspaces; however, it marks only the ports in the cluster IPspace as degraded.

- CRC monitor: Monitors the CRC statistics on the ports

This health monitor does not mark a port as degraded but generates an EMS message when a very high CRC failure rate is observed.

3. Enable or disable any of the health monitors for an IPspace as desired by using the `network options port-health-monitor modify` command.

4. View the detailed health of a port:

```
network port show -health
```

The command output displays the health status of the port, ignore health status setting, and list of reasons the port is marked as degraded.

A port health status can be healthy or degraded.

If the ignore health status setting is true, it indicates that the port health status has been modified from degraded to healthy by the administrator.

If the ignore health status setting is false, the port health status is determined automatically by the system.

### **Monitor the reachability of network ports in ONTAP 9.8 and later**

Reachability monitoring is built into ONTAP 9.8 and later. Use this monitoring to identify when the physical network topology does not match the ONTAP configuration. In some cases, ONTAP can repair port reachability. In other cases, additional steps are required.

## About this task

Use these commands to verify, diagnose, and repair network misconfigurations that stem from the ONTAP configuration not matching either the physical cabling or the network switch configuration.

### Step

1. View port reachability:

```
network port reachability show
```

2. Use the following decision tree and table to determine the next step, if any.

| Reachability-status | Description |
|---------------------|-------------|
|---------------------|-------------|

|                            |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
|----------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

|                           |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
|---------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| multi-domain-reachability | <p>The port has layer 2 reachability to its assigned broadcast domain; however, it also has layer 2 reachability to at least one other broadcast domain.</p> <p>Examine the physical connectivity and switch configuration to determine if it is incorrect or if the port's assigned broadcast domain needs to be merged with one or more broadcast domains.</p> <p>For more information, see <a href="#">Merge broadcast domains</a> or <a href="#">Repair port reachability</a>.</p> |
| unknown                   | If the reachability-status is "unknown", then wait a few minutes and try the command again.                                                                                                                                                                                                                                                                                                                                                                                            |

After you repair a port, you need to check for and resolve displaced LIFs and VLANs. If the port was part of an interface group, you also need to understand what happened to that interface group. For more information, see [Repair port reachability](#).

### Convert 40GbE NIC ports into multiple 10GbE ports for 10GbE connectivity

You can convert the X1144A-R6 and the X91440A-R6 40GbE Network Interface Cards (NICs) to support four 10GbE ports.

If you are connecting a hardware platform that supports one of these NICs to a cluster that supports 10GbE cluster interconnect and customer data connections, the NIC must be converted to provide the necessary 10GbE connections.

#### Before you begin

You must be using a supported breakout cable.

#### About this task

For a complete list of platforms that support NICs, see the [Hardware Universe](#).

On the X1144A-R6 NIC, only port A can be converted to support the four 10GbE connections. Once port A is converted, port e is not available for use.

#### Steps

1. Enter maintenance mode.
2. Convert the NIC from 40GbE support to 10GbE support.

```
nicadmin convert -m [40G | 10G] [port-name]
```

3. After using the convert command, halt the node.
4. Install or change the cable.
5. Depending on the hardware model, use the SP (Service Processor) or BMC (Baseboard Management Controller) to power-cycle the node for the conversion to take effect.

#### Removing a NIC from the node on ONTAP 9.7 or earlier

This topic applies to ONTAP 9.7 or earlier. You might have to remove a faulty NIC from its

slot or move the NIC to another slot for maintenance purposes.

### Before you begin

- All LIFs hosted on the NIC ports must have been migrated or deleted.
- None of the NIC ports can be the home ports of any LIFs.
- You must have advanced privileges to delete the ports from a NIC.

### Steps

1. Delete the ports from the NIC:

```
network port delete
```

2. Verify that the ports have been deleted:

```
network port show
```

3. Repeat step 1, if the output of the network port show command still shows the deleted port.

### Removing a NIC from the node on ONTAP 9.8 or later

This topic applies to ONTAP 9.8 or later. You might have to remove a faulty NIC from its slot or move the NIC to another slot for maintenance purposes.

### Steps

1. Power down the node.
2. Physically remove the NIC from its slot.
3. Power on the node.
4. Verify that the port has been deleted:

```
network port show
```

ONTAP automatically removes the port from any interface groups. If the port was the only member of an interface group, the interface group is deleted.

5. If the port had any VLANs configured on it, they are displaced. You can view displaced VLANs using the following command:

```
cluster controller-replacement network displaced-vlans show
```

The `displaced-interface show`, `displaced-vlans show`, and `displaced-vlans restore` commands are unique and do not require the fully qualified command name, which starts with `cluster controller-replacement network`.

6. These VLANs are deleted, but can be restored using the following command:

```
displaced-vlans restore
```

7. If the port had any LIFs configured on it, ONTAP automatically chooses new home ports for those LIFs on another port in the same broadcast domain. If no suitable home port is found on the same filer, those LIFs are considered displaced. You can view displaced LIFs using the following command:

```
displaced-interface show
```

8. When a new port is added to the broadcast domain on the same node, the home ports for the LIFs are automatically restored. Alternatively, you can either set the home port using `network interface modify -home-port -home-node` or use the `displaced-interface restore` command.

## Configure IPspaces (cluster administrators only)

### Overview

IPspaces enable you to configure a single ONTAP cluster so that it can be accessed by clients from more than one administratively separate network domain, even if those clients are using the same IP address subnet range. This allows for separation of client traffic for privacy and security.

An IPspace defines a distinct IP address space in which storage virtual machines (SVMs) reside. Ports and IP addresses defined for an IPspace are applicable only within that IPspace. A distinct routing table is maintained for each SVM within an IPspace; therefore, no cross-SVM or cross-IPspace traffic routing occurs.

IPspaces support both IPv4 and IPv6 addresses on their routing domains.

If you are managing storage for a single organization, then you do not need to configure IPspaces. If you are managing storage for multiple companies on a single ONTAP cluster, and you are certain that none of your customers have conflicting networking configurations, then you also do not need to use IPspaces. In many cases, the use of storage virtual machines (SVMs), with their own distinct IP routing tables, can be used to segregate unique networking configurations instead of using IPspaces.

### Example of using IPspaces

A common application for using IPspaces is when a Storage Service Provider (SSP) needs to connect customers of companies A and B to an ONTAP cluster on the SSP's premises and both companies are using the same private IP address ranges.

The SSP creates SVMs on the cluster for each customer and provides a dedicated network path from two SVMs to company A's network and from the other two SVMs to company B's network.

This type of deployment is shown in the following illustration, and it works if both companies use non-private IP address ranges. However, the illustration shows both companies using the same private IP address ranges, which causes problems.

Both companies use the private IP address subnet 10.0.0.0, causing the following problems:

- The SVMs in the cluster at the SSP location have conflicting IP addresses if both companies decide to use the same IP address for their respective SVMs.
- Even if the two companies agree on using different IP addresses for their SVMs, problems can arise.
- For example, if any client in A's network has the same IP address as a client in B's network, packets destined for a client in A's address space might get routed to a client in B's address space, and vice versa.
- If the two companies decide to use mutually exclusive address spaces (for example, A uses 10.0.0.0 with a network mask of 255.128.0.0 and B uses 10.128.0.0 with a network mask of 255.128.0.0), the SSP needs to configure static routes on the cluster to route traffic appropriately to A's and B's networks.
- This solution is neither scalable (because of static routes) nor secure (broadcast traffic is sent to all interfaces of the cluster). To overcome these problems, the SSP defines two IPspaces on the cluster—one for each company. Because no cross-IPspace traffic is routed, the data for each company is securely routed to its respective network even if all of the SVMs are configured in the 10.0.0.0 address space, as

shown in the following illustration:

Additionally, the IP addresses referred to by the various configuration files, such as the `/etc/hosts` file, the `/etc/hosts.equiv` file, and the `/etc/rc` file, are relative to that IPspace. Therefore, the IPspaces enable the SSP to configure the same IP address for the configuration and authentication data for multiple SVMs, without conflict.

### Standard properties of IPspaces

Special IPspaces are created by default when the cluster is first created. Additionally, special storage virtual machines (SVMs) are created for each IPspace.

Two IPspaces are created automatically when the cluster is initialized:

- "Default" IPspace

This IPspace is a container for ports, subnets, and SVMs that serve data. If your configuration does not need separate IPspaces for clients, all SVMs can be created in this IPspace. This IPspace also contains the cluster management and node management ports.

- "Cluster" IPspace

This IPspace contains all cluster ports from all nodes in the cluster. It is created automatically when the cluster is created. It provides connectivity to the internal private cluster network. As additional nodes join the cluster, cluster ports from those nodes are added to the "Cluster" IPspace.

A "system" SVM exists for each IPspace. When you create an IPspace, a default system SVM of the same name is created:

- The system SVM for the "Cluster" IPspace carries cluster traffic between nodes of a cluster on the internal private cluster network.

It is managed by the cluster administrator, and it has the name "Cluster".

- The system SVM for the "Default" IPspace carries management traffic for the cluster and nodes, including the intercluster traffic between clusters.

It is managed by the cluster administrator, and it uses the same name as the cluster.

- The system SVM for a custom IPspace that you create carries management traffic for that SVM.

It is managed by the cluster administrator, and it uses the same name as the IPspace.

One or more SVMs for clients can exist in an IPspace. Each client SVM has its own data volumes and configurations, and it is administered independently of other SVMs.

## Create IPspaces

IPspaces are distinct IP address spaces in which storage virtual machines (SVMs) reside. You can create IPspaces when you need your SVMs to have their own secure storage, administration, and routing.

### About this task

There is a cluster-wide limit of 512 IPspaces. The cluster-wide limit is reduced to 256 IPspaces for clusters that contain nodes with 6 GB of RAM or less for platforms such as FAS2220 or FAS2240. See the Hardware Universe to determine whether additional limits apply to your platform.

### NetApp Hardware Universe

An IPspace name cannot be "all" because "all" is a system-reserved name.

### Step

Create an IPspace:

```
network ipspace create -ipspace ipspace_name
```

`ipspace_name` is the name of the IPspace that you want to create. The following command creates the

IPspace ipspace1 on a cluster:

```
network ipspace create -ipspace ipspace1
```

### After you finish

If you create an IPspace in a cluster with a MetroCluster configuration, IPspace objects must be manually replicated to the partner clusters. Any SVMs that are created and assigned to an IPspace before the IPspace is replicated will not be replicated to the partner clusters.

Broadcast domains are created automatically in the "Default" IPspace and can be moved between IPspaces using the following command:

```
network port broadcast-domain move
```

For example, if you want to move a broadcast domain from "Default" to "ips1", using the following command:

```
network port broadcast-domain move -ipspace Default -broadcast-domain Default -to-ipspace ips1
```

### Display IPspaces

You can display the list of IPspaces that exist in a cluster, and you can view the storage virtual machines (SVMs), broadcast domains, and ports that are assigned to each IPspace.

#### Step

Display the IPspaces and SVMs in a cluster:

```
network ipspace show [-ipspace ipspace_name]
```

The following command displays all of the IPspaces, SVMs, and broadcast domains in the cluster:

| IPspace  | Vserver List       | Broadcast Domains |
|----------|--------------------|-------------------|
| Default  | vs1, cluster-1     | Default           |
| ipspace1 | vs3, vs4, ipspace1 | bcast1            |

The following command displays the nodes and ports that are part of IPspace ipspace1:

```
network ipspace show -ipspace ipspace1
IPspace name: ipspace1
Ports: cluster-1-01:e0c, cluster-1-01:e0d, cluster-1-01:e0e, cluster-1-02:e0c, cluster-1-02:e0d, cluster-1-02:e0e
Broadcast Domains: Default-1
Vservers: vs3, vs4, ipspace1
```

## Delete an IPspace

If you no longer need an IPspace, you can delete it.

### Before you begin

There must be no broadcast domains, network interfaces, or SVMs associated with the IPspace you want to delete.

The system-defined "Default" and "Cluster" IPspaces cannot be deleted.

### Step

Delete an IPspace:

```
network ipspace delete -ipspace ipspace_name
```

The following command deletes IPspace ipspace1 from the cluster:

```
network ipspace delete -ipspace ipspace1
```

## Configure broadcast domains (cluster administrators only)

### ONTAP 9.8 and later

#### About broadcast domains for ONTAP 9.8 and later

Broadcast domains are intended to group network ports that belong to the same layer 2 network. The ports in the group can then be used by a storage virtual machine (SVM) for data or management traffic.

A broadcast domain resides in an IPspace. During cluster initialization, the system creates two default broadcast domains:

- The "Default" broadcast domain contains ports that are in the "Default" IPspace.

These ports are used primarily to serve data. Cluster management and node management ports are also in this broadcast domain.

- The "Cluster" broadcast domain contains ports that are in the "Cluster" IPspace.

These ports are used for cluster communication and include all cluster ports from all nodes in the cluster.

The system creates additional broadcast domains in the Default IPspace when necessary. The "Default" broadcast domain contains the home-port of the management LIF, plus any other ports that have layer 2 reachability to that port. Additional broadcast domains are named "Default-1", "Default-2", and so forth.

#### Example of using broadcast domains

A broadcast domain is a set of network ports in the same IPspace that also has layer 2 reachability to one another, typically including ports from many nodes in the cluster.

The illustration shows the ports assigned to three broadcast domains in a four-node cluster:

- The "Cluster" broadcast domain is created automatically during cluster initialization, and it contains ports a and b from each node in the cluster.
- The "Default" broadcast domain is also created automatically during cluster initialization, and it contains ports c and d from each node in the cluster.
- The system automatically creates any additional broadcast domains during cluster initialization based on layer 2 network reachability. These additional broadcast domains are named Default-1, Default-2, and so forth.

A failover group of the same name and with the same network ports as each of the broadcast domains is created automatically. This failover group is automatically managed by the system, meaning that as ports are added or removed from the broadcast domain, they are automatically added or removed from this failover group.

#### Add a broadcast domain

Broadcast domains group network ports in the cluster that belong to the same layer 2

network. The ports can then be used by SVMs.

Beginning with ONTAP 9.8, broadcast domains are automatically created during the cluster create or join operation. Beginning with ONTAP 9.12.0, in addition to the automatically created broadcast domains, you can manually add a broadcast domain in System Manager.

### Before you begin

The ports you plan to add to the broadcast domain must not belong to another broadcast domain. If the ports you want to use belong to another broadcast domain, but are unused, remove those ports from the original broadcast domain.

### About this task

- All broadcast domain names must be unique within an IPspace.
- The ports added to a broadcast domain can be physical network ports, VLANs, or link aggregation groups/interface groups (LAGs/ifgrps).
- The maximum transmission unit (MTU) of the ports added to a broadcast domain are updated to the MTU value set in the broadcast domain.
- The MTU value must match all the devices connected to that layer 2 network except for the e0M port handling management traffic.
- If you do not specify an IPspace name, the broadcast domain is created in the "Default" IPspace.

To make system configuration easier, a failover group of the same name is created automatically that contains the same ports.

## System Manager

### Steps

1. Select **Network > Overview > Broadcast domain**.
2. Click  **Add**
3. Name the broadcast domain.
4. Set the MTU.
5. Select the IPspace.
6. Save the broadcast domain.

You can edit or delete a broadcast domain after it has been added.

## CLI

In ONTAP 9.7 or earlier, you can manually create a broadcast domain.

### Steps

1. View the ports that are not currently assigned to a broadcast domain:

```
network port show
```

If the display is large, use the `network port show -broadcast-domain` command to view only unassigned ports.

2. Create a broadcast domain:

```
network port broadcast-domain create -broadcast-domain
broadcast_domain_name -mtu mtu_value [-ipspace ipspace_name] [-ports
ports_list]
```

- `broadcast_domain_name` is the name of the broadcast domain you want to create.
- `mtu_value` is the MTU size for IP packets; 1500 and 9000 are typical values.

This value is applied to all ports that are added to this broadcast domain.

- `ipspace_name` is the name of the IPspace to which this broadcast domain will be added.

The "Default" IPspace is used unless you specify a value for this parameter.

- `ports_list` is the list of ports that will be added to the broadcast domain.

The ports are added in the format `node_name:port_number`, for example, `node1:e0c`.

3. Verify that the broadcast domain was created as desired:

```
network port show -instance -broadcast-domain new_domain
```

### Example

The following command creates broadcast domain `bcast1` in the Default IPspace, sets the MTU to 1500, and adds four ports:

```
network port broadcast-domain create -broadcast-domain bcast1 -mtu 1500 -ports
cluster1-01:e0e,cluster1-01:e0f,cluster1-02:e0e,cluster1-02:e0f
```

### After you finish

You can define the pool of IP addresses that will be available in the broadcast domain by creating a subnet, or you can assign SVMs and interfaces to the IPspace at this time. For more information, see [Cluster and SVM peering](#).

If you need to change the name of an existing broadcast domain, use the `network port broadcast-domain rename` command.

### Add or remove ports from a broadcast domain

Broadcast domains are automatically created during the cluster create or join operation. You do not need to manually remove ports from broadcast domains.

If network port reachability has changed, either through physical network connectivity or switch configuration, and a network port belongs in a different broadcast domain, see the following topic:

[Repair port reachability](#)

### Split broadcast domains

If network port reachability has changed, either through physical network connectivity or switch configuration, and a group of network ports previously configured in a single broadcast domain has become partitioned into two different reachability sets, you can split a broadcast domain to synchronize the ONTAP configuration with the physical network topology.

To determine if a network port broadcast domain is partitioned into more than one reachability set, use the `network port reachability show -details` command and pay attention to which ports do not have connectivity to one another ("Unreachable ports"). Typically, the list of unreachable ports defines the set of ports that should be split into another broadcast domain, after you have verified that the physical and switch configuration is accurate.

### Step

Split a broadcast domain into two broadcast domains:

```
network port broadcast-domain split -ipspace <ipspace_name> -broadcast
-domain <broadcast_domain_name> -new-broadcast-domain
<broadcast_domain_name> -ports <node:port,node:port>
```

- `ipspace_name` is the name of the ipspace where the broadcast domain resides.
- `-broadcast-domain` is the name of the broadcast domain that will be split.
- `-new-broadcast-domain` is the name of the new broadcast domain that will be created.
- `-ports` is the node name and port to be added to the new broadcast domain.

## Merge broadcast domains

If network port reachability has changed, either through physical network connectivity or switch configuration, and two group of network ports previously configured in multiple broadcast domains now all share reachability, then merging two broadcast domains can be used to synchronize the ONTAP configuration with the physical network topology.

To determine if multiple broadcast domains belong to one reachability set, use the "network port reachability show -details" command and pay attention to which ports that are configured in another broadcast domain actually have connectivity to one another ("Unexpected ports"). Typically, the list of unexpected ports defines the set of ports that should be merged into the broadcast domain after you have verified that the physical and switch configuration is accurate.

### Step

Merge the ports from one broadcast domain into an existing broadcast domain:

```
network port broadcast-domain merge -ipspace <ipspace_name> -broadcast
-domain <broadcast_domain_name> -into-broadcast-domain
<broadcast_domain_name>
```

- `ipspace_name` is the name of the ipspace where the broadcast domains reside.
- `-broadcast-domain` is the name of the broadcast domain that will be merged.
- `-into-broadcast-domain` is the name of the broadcast domain that will receive additional ports.

## Change the MTU value for ports in a broadcast domain

You can modify the MTU value for a broadcast domain to change the MTU value for all ports in that broadcast domain. This can be done to support topology changes that have been made in the network.

### Before you begin

The MTU value must match all the devices connected to that layer 2 network except for the e0M port handling management traffic.

### About this task

Changing the MTU value causes a brief interruption in traffic over the affected ports. The system displays a prompt that you must answer with `y` to make the MTU change.

### Step

Change the MTU value for all ports in a broadcast domain:

```
network port broadcast-domain modify -broadcast-domain
<broadcast_domain_name> -mtu <mtu_value> [-ipspace <ipspace_name>]
```

- `broadcast_domain` is the name of the broadcast domain.
- `mtu` is the MTU size for IP packets; 1500 and 9000 are typical values.

- `ipspace` is the name of the IPspace in which this broadcast domain resides. The "Default" IPspace is used unless you specify a value for this option. The following command changes the MTU to 9000 for all ports in the broadcast domain `bcast1`:

```
network port broadcast-domain modify -broadcast-domain <Default-1> -mtu <9000>
Warning: Changing broadcast domain settings will cause a momentary data-serving interruption.
Do you want to continue? {y|n}: <y>
```

### Display broadcast domains

You can display the list of broadcast domains within each IPspace in a cluster. The output also shows the list of ports and the MTU value for each broadcast domain.

#### Step

Display the broadcast domains and associated ports in the cluster:

```
network port broadcast-domain show
```

The following command displays all the broadcast domains and associated ports in the cluster:

| network port broadcast-domain show |             |      |                                                                                                                      |
|------------------------------------|-------------|------|----------------------------------------------------------------------------------------------------------------------|
| IPspace Broadcast                  |             |      | Update                                                                                                               |
| Name                               | Domain Name | MTU  | Port List                                                                                                            |
| -----                              |             |      |                                                                                                                      |
| Cluster                            | Cluster     | 9000 | cluster-1-01:e0a<br>cluster-1-01:e0b<br>cluster-1-02:e0a<br>cluster-1-02:e0b                                         |
|                                    |             |      | complete<br>complete<br>complete<br>complete                                                                         |
| Default                            | Default     | 1500 | cluster-1-01:e0c<br>cluster-1-01:e0d<br>cluster-1-02:e0c<br>cluster-1-02:e0d                                         |
|                                    |             |      | complete<br>complete<br>complete<br>complete                                                                         |
|                                    | Default-1   | 1500 | cluster-1-01:e0e<br>cluster-1-01:e0f<br>cluster-1-01:e0g<br>cluster-1-02:e0e<br>cluster-1-02:e0f<br>cluster-1-02:e0g |
|                                    |             |      | complete<br>complete<br>complete<br>complete<br>complete<br>complete                                                 |

The following command displays the ports in the Default-1 broadcast domain that have an update status of error, which indicate that the port could not be updated properly:

```
network port broadcast-domain show -broadcast-domain Default-1 -port
-update-status error
```

| IPspace Broadcast |             |      |                  | Update         |
|-------------------|-------------|------|------------------|----------------|
| Name              | Domain Name | MTU  | Port List        | Status Details |
| Default           | Default-1   | 1500 | cluster-1-02:e0g | error          |

For more information, see [ONTAP 9 commands](#).

#### Delete a broadcast domain

If you no longer need a broadcast domain, you can delete it. This moves the ports associated with that broadcast domain to the "Default" IPspace.

#### Before you begin

There must be no subnets, network interfaces, or SVMs associated with the broadcast domain you want to delete.

#### About this task

- The system-created "Cluster" broadcast domain cannot be deleted.
- All failover groups related to the broadcast domain are removed when you delete the broadcast domain.

The procedure you follow depends on the interface that you use—System Manager or the CLI:

## System Manager

Beginning with ONTAP 9.12.0, you can use System Manager to delete a broadcast domain

The delete option is not shown when the broadcast domain contains ports or is associated with a subnet.

### Steps

1. Select **Network > Overview > Broadcast domain**.
2. Select  > **Delete** beside the broadcast domain you want to remove.

### CLI

Use the CLI to delete a broadcast domain

#### Step

Delete a broadcast domain:

```
network port broadcast-domain delete -broadcast-domain broadcast_domain_name
[-ipspace ipspace_name]
```

The following command deletes broadcast domain Default-1 in IPspace ipspace1:

```
network port broadcast-domain delete -broadcast-domain Default-1 -ipspace
ipspace1
```

## ONTAP 9.7 and earlier

### Overview for ONTAP 9.7 and earlier

Broadcast domains are intended to group network ports that belong to the same layer 2 network. The ports in the group can then be used by a storage virtual machine (SVM) for data or management traffic.

A broadcast domain resides in an IPspace. During cluster initialization, the system creates two default broadcast domains:

- The Default broadcast domain contains ports that are in the Default IPspace.  
These ports are used primarily to serve data. Cluster management and node management ports are also in this broadcast domain.
- The Cluster broadcast domain contains ports that are in the Cluster IPspace.  
These ports are used for cluster communication and include all cluster ports from all nodes in the cluster.

If you have created unique IPspaces to separate client traffic, then you need to create a broadcast domain in each of those IPspaces.

Create a broadcast domain to group network ports in the cluster that belong to the same layer 2 network. The ports can then be used by SVMs.

### Example of using broadcast domains

A broadcast domain is a set of network ports in the same IPspace that also has layer 2

reachability to one another, typically including ports from many nodes in the cluster.

The illustration shows the ports assigned to three broadcast domains in a four-node cluster:

- The Cluster broadcast domain is created automatically during cluster initialization, and it contains ports a and b from each node in the cluster.
- The Default broadcast domain is also created automatically during cluster initialization, and it contains ports c and d from each node in the cluster.
- The bcast1 broadcast domain has been created manually, and it contains ports e, f, and g from each node in the cluster.

This broadcast domain was created by the system administrator specifically for a new client to access data through a new SVM.

A failover group of the same name and with the same network ports as each of the broadcast domains is created automatically. This failover group is automatically managed by the system, meaning that as ports are added or removed from the broadcast domain, they are automatically added or removed from this failover group.

#### Create a broadcast domain

In ONTAP 9.7 and earlier, you create a broadcast domain to group network ports in the cluster that belong to the same layer 2 network. The ports can then be used by SVMs.

#### Before you begin

Beginning with ONTAP 9.8, broadcast domains are automatically created during the cluster create or join operation. If you are running ONTAP 9.8 or later, these steps are not needed.

In ONTAP 9.7 and earlier, the ports you plan to add to the broadcast domain must not belong to another broadcast domain.

#### About this task

- All broadcast domain names must be unique within an IPspace.
- The ports added to a broadcast domain can be physical network ports, VLANs, or interface groups (ifgrps).
- If the ports you want to use belong to another broadcast domain, but are unused, you use the `network port broadcast-domain remove-ports` command to remove the ports from the existing broadcast

domain.

- The MTU of the ports added to a broadcast domain are updated to the MTU value set in the broadcast domain.
- The MTU value must match all of the devices connected to that layer 2 network except for the e0M port handling management traffic.
- If you do not specify an IPspace name, the broadcast domain is created in the "Default" IPspace.

To make system configuration easier, a failover group of the same name is created automatically that contains the same ports.

## Steps

1. View the ports that are not currently assigned to a broadcast domain:

```
network port show
```

If the display is large, use the `network port show -broadcast-domain` command to view only unassigned ports.

2. Create a broadcast domain:

```
network port broadcast-domain create -broadcast-domain broadcast_domain_name
-mtu mtu_value [-ipspace ipspace_name] [-ports ports_list]
```

- `broadcast_domain_name` is the name of the broadcast domain you want to create.
- `mtu_value` is the MTU size for IP packets; 1500 and 9000 are typical values.

This value is applied to all ports that are added to this broadcast domain.

- `ipspace_name` is the name of the IPspace to which this broadcast domain will be added.

The "Default" IPspace is used unless you specify a value for this parameter.

- `ports_list` is the list of ports that will be added to the broadcast domain.

The ports are added in the format `node_name:port_number`, for example, `node1:e0c`.

3. Verify that the broadcast domain was created as desired:

```
network port show -instance -broadcast-domain new_domain
```

## Example

The following command creates broadcast domain `bcast1` in the Default IPspace, sets the MTU to 1500, and adds four ports:

```
network port broadcast-domain create -broadcast-domain bcast1 -mtu 1500 -ports
cluster1-01:e0e,cluster1-01:e0f,cluster1-02:e0e,cluster1-02:e0f
```

## After you finish

You can define the pool of IP addresses that will be available in the broadcast domain by creating a subnet, or you can assign SVMs and interfaces to the IPspace at this time. For more information, see [Cluster and SVM peering](#).

If you need to change the name of an existing broadcast domain, you use the `network port broadcast-domain rename` command.

#### Add or remove ports from a broadcast domain

You can add network ports when initially creating a broadcast domain, or you can add ports to, or remove ports from, a broadcast domain that already exists. This allows you to efficiently use all the ports in the cluster.

#### Before you begin

- Ports you plan to add to a broadcast domain must not belong to another broadcast domain.
- Ports that already belong to an interface group cannot be added individually to a broadcast domain.

#### About this task

The following rules apply when adding and removing network ports:

| When adding ports...                                                              | When removing ports...                                                           |
|-----------------------------------------------------------------------------------|----------------------------------------------------------------------------------|
| The ports can be network ports, VLANs, or interface groups (ifgrps).              | N/A                                                                              |
| The ports are added to the system-defined failover group of the broadcast domain. | The ports are removed from all failover groups in the broadcast domain.          |
| The MTU of the ports is updated to the MTU value set in the broadcast domain.     | The MTU of the ports is unchanged.                                               |
| The IPspace of the ports is updated to the IPspace value of the broadcast domain. | The ports are moved to the 'Default' IPspace with no broadcast domain attribute. |

If you remove the last member port of an interface group using the `network port ifgrp remove-port` command, it causes the interface group port to be removed from the broadcast domain because an empty interface group port is not allowed in a broadcast domain.

#### Steps

- Display the ports that are currently assigned or unassigned to a broadcast domain by using the `network port show` command.
- Add or remove network ports from the broadcast domain:

| If you want to...                    | Use...                                                  |
|--------------------------------------|---------------------------------------------------------|
| Add ports to a broadcast domain      | <code>network port broadcast-domain add-ports</code>    |
| Remove ports from a broadcast domain | <code>network port broadcast-domain remove-ports</code> |

For more information about these commands, see [ONTAP 9 commands](#).

#### Examples of adding and removing ports

The following command adds port e0g on node cluster-1-01 and port e0g on node cluster-1-02 to broadcast

domain bcast1 in the Default IPspace:

```
cluster-1::> network port broadcast-domain add-ports -broadcast-domain bcast1
-ports cluster-1-01:e0g,cluster1-02:e0g
```

The following command adds two cluster ports to broadcast domain Cluster in the Cluster IPspace:

```
cluster-1::> network port broadcast-domain add-ports -broadcast-domain Cluster
-ports cluster-2-03:e0f,cluster2-04:e0f -ipspace Cluster
```

The following command removes port e0e on node cluster1-01 from broadcast domain bcast1 in the Default IPspace:

```
cluster-1::> network port broadcast-domain remove-ports -broadcast-domain bcast1
-ports cluster-1-01:e0e
```

### Split broadcast domains

You can modify an existing broadcast domain by splitting it into two different broadcast domains, with each broadcast domain containing some of the original ports assigned to the original broadcast domain.

#### About this task

- If the ports are in a failover group, all of the ports in a failover group must be split.
- If the ports have LIFs associated with them, the LIFs cannot be part of a subnet's ranges.

#### Step

Split a broadcast domain into two broadcast domains:

```
network port broadcast-domain split -ipspace <ipspace_name> -broadcast
-domain <broadcast_domain_name> -new-broadcast-domain
<broadcast_domain_name> -ports <node:port,node:port>
```

- `ipspace_name` is the name of the IPspace where the broadcast domain resides.
- `-broadcast-domain` is the name of the broadcast domain that will be split.
- `-new-broadcast-domain` is the name of the new broadcast domain that will be created.
- `-ports` is the node name and port to be added to the new broadcast domain.

### Merge broadcast domains

You can move all of the ports from one broadcast domain into an existing broadcast domain using the merge command.

This operation reduces the steps required if you were to remove all ports from a broadcast domain and then add the ports to an existing broadcast domain.

#### Step

Merge the ports from one broadcast domain into an existing broadcast domain:

```
network port broadcast-domain merge -ipspace <ipspace_name> -broadcast
-domain <broadcast_domain_name> -into-broadcast-domain
<broadcast_domain_name>
```

- `ipspace_name` is the name of the IPspace where the broadcast domains reside.
- `-broadcast-domain` is the name of the broadcast domain that will be merged.
- `-into-broadcast-domain` is the name of the broadcast domain that will receive additional ports.

## Example

The following example merges broadcast domain `bd-data1` into broadcast domain `bd-data2`:

```
network port -ipspace Default broadcast-domain bd-data1 into-broadcast-domain bd-
data2
```

## Change the MTU value for ports in a broadcast domain

You can modify the MTU value for a broadcast domain to change the MTU value for all ports in that broadcast domain. This can be done to support topology changes that have been made in the network.

### Before you begin

The MTU value must match all the devices connected to that layer 2 network except for the e0M port handling management traffic.

### About this task

Changing the MTU value causes a brief interruption in traffic over the affected ports. The system displays a prompt that you must answer with `y` to make the MTU change.

### Step

Change the MTU value for all ports in a broadcast domain:

```
network port broadcast-domain modify -broadcast-domain
<broadcast_domain_name> -mtu <mtu_value> [-ipspace <ipspace_name>]
```

- `broadcast_domain` is the name of the broadcast domain.
- `mtu` is the MTU size for IP packets; 1500 and 9000 are typical values.
- `ipspace` is the name of the IPspace in which this broadcast domain resides. The "Default" IPspace is used unless you specify a value for this option. The following command changes the MTU to 9000 for all ports in the broadcast domain `bcast1`:

```
network port broadcast-domain modify -broadcast-domain <Default-1> -mtu <9000>
Warning: Changing broadcast domain settings will cause a momentary data-serving interruption.
Do you want to continue? {y|n}: <y>
```

### Display broadcast domains

You can display the list of broadcast domains within each IPspace in a cluster. The output also shows the list of ports and the MTU value for each broadcast domain.

#### Step

Display the broadcast domains and associated ports in the cluster:

```
network port broadcast-domain show
```

The following command displays all the broadcast domains and associated ports in the cluster:

| network port broadcast-domain show |             |      |                                                                                                                      |
|------------------------------------|-------------|------|----------------------------------------------------------------------------------------------------------------------|
| IPspace Broadcast                  |             |      | Update                                                                                                               |
| Name                               | Domain Name | MTU  | Port List                                                                                                            |
| -----                              |             |      |                                                                                                                      |
| Cluster                            | Cluster     | 9000 | cluster-1-01:e0a<br>cluster-1-01:e0b<br>cluster-1-02:e0a<br>cluster-1-02:e0b                                         |
| Default                            | Default     | 1500 | cluster-1-01:e0c<br>cluster-1-01:e0d<br>cluster-1-02:e0c<br>cluster-1-02:e0d                                         |
|                                    | bcast1      | 1500 | cluster-1-01:e0e<br>cluster-1-01:e0f<br>cluster-1-01:e0g<br>cluster-1-02:e0e<br>cluster-1-02:e0f<br>cluster-1-02:e0g |

The following command displays the ports in the bcast1 broadcast domain that have an update status of error, which indicate that the port could not be updated properly:

```
network port broadcast-domain show -broadcast-domain bcast1 -port-update
-status error
```

| IPspace Broadcast |             |      |                  | Update         |
|-------------------|-------------|------|------------------|----------------|
| Name              | Domain Name | MTU  | Port List        | Status Details |
| Default           | bcast1      | 1500 | cluster-1-02:e0g | error          |

For more information, see [ONTAP 9 commands](#).

#### Delete a broadcast domain

If you no longer need a broadcast domain, you can delete it. This moves the ports associated with that broadcast domain to the "Default" IPspace.

#### Before you begin

There must be no subnets, network interfaces, or SVMs associated with the broadcast domain you want to delete.

#### About this task

- The system-created "Cluster" broadcast domain cannot be deleted.
- All failover groups related to the broadcast domain are removed when you delete the broadcast domain.

#### Step

Delete a broadcast domain:

```
network port broadcast-domain delete -broadcast-domain
<broadcast_domain_name> [-ipspace <ipspace_name>]
```

The following command deletes broadcast domain bcast1 in IPspace ipspace1:

```
network port broadcast-domain delete -broadcast-domain <bcast1> -ipspace
<ipspace1>
```

## Configure failover groups and policies for LIFs

#### Overview

LIF failover refers to the automatic migration of a LIF to a different network port in response to a link failure on the LIF's current port. This is a key component to providing high availability for the connections to SVMs. Configuring LIF failover involves creating a failover group, modifying the LIF to use the failover group, and specifying a failover policy.

A failover group contains a set of network ports (physical ports, VLANs, and interface groups) from one or

more nodes in a cluster. The network ports that are present in the failover group define the failover targets available for the LIF. A failover group can have cluster management, node management, intercluster, and NAS data LIFs assigned to it.

When a LIF is configured without a valid failover target, an outage occurs when the LIF attempts to fail over. You can use the "network interface show -failover" command to verify the failover configuration.

When you create a broadcast domain, a failover group of the same name is created automatically that contains the same network ports. This failover group is automatically managed by the system, meaning that as ports are added or removed from the broadcast domain, they are automatically added or removed from this failover group. This is provided as an efficiency for administrators who do not want to manage their own failover groups.

### Create a failover group

You create a failover group of network ports so that a LIF can automatically migrate to a different port if a link failure occurs on the LIF's current port. This enables the system to reroute network traffic to other available ports in the cluster.

#### About this task

You use the `network interface failover-groups create` command to create the group and to add ports to the group.

- The ports added to a failover group can be network ports, VLANs, or interface groups (ifgrps).
- All the ports added to the failover group must belong to the same broadcast domain.
- A single port can reside in multiple failover groups.
- If you have LIFs in different VLANs or broadcast domains, you must configure failover groups for each VLAN or broadcast domain.
- Failover groups do not apply in SAN iSCSI or FC environments.

#### Step

Create a failover group:

```
network interface failover-groups create -vserver vserver_name -failover-group failover_group_name -targets ports_list
```

- `vserver_name` is the name of the SVM that can use the failover group.
- `failover_group_name` is the name of the failover group you want to create.
- `ports_list` is the list of ports that will be added to the failover group.  
Ports are added in the format `node_name:<port_number>`, for example, `node1:e0c`.

The following command creates failover group fg3 for SVM vs3 and adds two ports:

```
network interface failover-groups create -vserver vs3 -failover-group fg3 -targets cluster1-01:e0e,cluster1-02:e0e
```

#### After you finish

- You should apply the failover group to a LIF now that the failover group has been created.
- Applying a failover group that does not provide a valid failover target for a LIF results in a warning message.

If a LIF that does not have a valid failover target attempts to fail over, an outage might occur.

## Configure failover settings on a LIF

You can configure a LIF to fail over to a specific group of network ports by applying a failover policy and a failover group to the LIF. You can also disable a LIF from failing over to another port.

### About this task

- When a LIF is created, LIF failover is enabled by default, and the list of available target ports is determined by the default failover group and failover policy based on the LIF type and service policy.

Beginning with 9.5, you can specify a service policy for the LIF that defines which network services can use the LIF. Some network services impose failover restrictions on a LIF.

If a LIF's service policy is changed in a way that further restricts failover, the LIF's failover policy is automatically updated by the system.

- You can modify the failover behavior of LIFs by specifying values for the -failover-group and -failover-policy parameters in the network interface modify command.
- Modification of a LIF that results in the LIF having no valid failover target results in a warning message.

If a LIF that does not have a valid failover target attempts to fail over, an outage might occur.

- Beginning with ONTAP 9.11.1, on All SAN Array (ASA) platforms, iSCSI LIF failover is automatically enabled on newly created iSCSI LIFs on newly created storage VMs.

Additionally, you can manually enable iSCSI LIF failover on pre-existing iSCSI LIFs, meaning LIFs that were created prior to upgrading to ONTAP 9.11.1 or later.

### iSCSI LIF failover for ASA platforms

- The following list describes how the -failover-policy setting affects the target ports that are selected from the failover group:

For iSCSI LIF failover, only the failover policies local-only, sfo-partner-only and disabled are supported.

- broadcast-domain-wide applies to all ports on all nodes in the failover group.
- system-defined applies to only those ports on the LIF's home node and one other node in the cluster, typically a non-SFO partner, if it exists.
- local-only applies to only those ports on the LIF's home node.
- sfo-partner-only applies to only those ports on the LIF's home node and its SFO partner.
- disabled indicates the LIF is not configured for failover.

## Step

Configure failover settings for an existing interface:

```
network interface modify -vserver <vserver_name> -lif <lif_name> -failover
-policy <failover_policy> -failover-group <failover_group>
```

#### Examples of configuring failover settings and disabling failover

The following command sets the failover policy to broadcast-domain-wide and uses the ports in failover group fg3 as failover targets for LIF data1 on SVM vs3:

```
network interface modify -vserver vs3 -lif data1 failover-policy
broadcast-domain-wide - failover-group fg3
```

```
network interface show -vserver vs3 -lif * -fields failover-
group,failover-policy
```

| vserver | lif   | failover-policy       | failover-group |
|---------|-------|-----------------------|----------------|
| vs3     | data1 | broadcast-domain-wide | fg3            |

The following command disables failover for LIF data1 on SVM vs3:

```
network interface modify -vserver vs3 -lif data1 failover-policy disabled
```

#### Commands for managing failover groups and policies

You can use the `network interface failover-groups` commands to manage failover groups. You use the `network interface modify` command to manage the failover groups and failover policies that are applied to a LIF.

| If you want to...                          | Use this command...                                           |
|--------------------------------------------|---------------------------------------------------------------|
| Add network ports to a failover group      | <code>network interface failover-groups add-targets</code>    |
| Remove network ports from a failover group | <code>network interface failover-groups remove-targets</code> |
| Modify network ports in a failover group   | <code>network interface failover-groups modify</code>         |
| Display the current failover groups        | <code>network interface failover-groups show</code>           |

|                                                                               |                                                                             |
|-------------------------------------------------------------------------------|-----------------------------------------------------------------------------|
| Configure failover on a LIF                                                   | <code>network interface modify -failover-group -failover-policy</code>      |
| Display the failover group and failover policy that is being used by each LIF | <code>network interface show -fields failover-group, failover-policy</code> |
| Rename a failover group                                                       | <code>network interface failover-groups rename</code>                       |
| Delete a failover group                                                       | <code>network interface failover-groups delete</code>                       |

Modifying a failover group such that it does not provide a valid failover target for any LIF in the cluster can result in an outage when a LIF attempts to fail over.

For more information, see the man pages for the `network interface failover-groups` and `network interface modify` commands.

## Configure subnets (cluster administrators only)

### Overview

Subnets enable you to allocate specific blocks, or pools, of IP addresses for your ONTAP network configuration. This enables you to create LIFs more easily by specifying a subnet name instead of having to specify the IP address and network mask values.

A subnet is created within a broadcast domain, and it contains a pool of IP addresses that belong to the same layer 3 subnet. IP addresses in a subnet are allocated to ports in the broadcast domain when LIFs are created. When LIFs are removed, the IP addresses are returned to the subnet pool and are available for future LIFs.

It is recommended that you use subnets because they make the management of IP addresses much easier, and they make the creation of LIFs a simpler process. Additionally, if you specify a gateway when defining a subnet, a default route to that gateway is added automatically to the SVM when a LIF is created using that subnet.

### Create a subnet

You can create a subnet to allocate specific blocks of IPv4 or IPv6 addresses to be used later when you create LIFs for the SVM.

This enables you to create LIFs more easily by specifying a subnet name instead of having to specify IP address and network mask values for each LIF.

### Before you begin

You must be a cluster administrator to perform this task.

### Procedure

The procedure you follow depends on the interface that you use—System Manager or the CLI:

## System Manager

Beginning with ONTAP 9.12.0, you can use System Manager to create a subnet.

### Steps

1. Select **Network > Overview > Subnets**.
2. Click  **Add** to create a subnet.
3. Name the subnet.
4. Specify the subnet IP address.
5. Set the subnet mask.
6. Define the range of IP addresses that comprise the subnet.
7. If useful, specify a gateway.
8. Select the broadcast domain to which the subnet belongs.
9. Save your changes.
  - a. If the IP address or range entered is already used by an interface, the following message is displayed:  
An IP address in this range is already in use by a LIF. Associate the LIF with this subnet?  
b. When you click **OK**, the existing LIF will be associated with the subnet.

## CLI

Use the CLI to create a subnet.

### Steps

1. Create a subnet.

```
network subnet create -broadcast-domain ipspace1 -ipspace ipspace1 -subnet
-name ipspace1 -subnet 10.0.0.0/24 -gateway 10.0.0.1 -ip-ranges
"10.0.0.128-10.0.0.130,10.0.0.132"
```

The subnet name can be either a subnet IP value such as 192.0.2.0/24 or a string such as ipspace1 like the one used in this example.

2. Verify that the subnet configuration is correct.

The output from this example shows information about the subnet named ipspace1 in the ipspace1 IPspace. The subnet belongs to the broadcast domain name ipspace1. You can assign the IP addresses in this subnet to data LIFs for SVMs created in the ipspace1 IPspace.

```
network subnet show -ipspace ipspace1
```

## Add or remove IP addresses from a subnet

You can add IP addresses when initially creating a subnet, or you can add IP addresses to a subnet that already exists. You can also remove IP addresses from an existing subnet. This enables you to allocate only the required IP addresses for SVMs.

The procedure you follow depends on the interface that you use—System Manager or the CLI:

## System Manager

Beginning with ONTAP 9.12.0, you can use System Manager to add or remove IP addresses to or from a subnet

### Steps

1. Select **Network > Overview > Subnets**.
2. Select  > **Edit** beside the subnet you want to change.
3. Add or remove IP addresses.
4. Save your changes.
  - a. If the IP address or range entered is already used by an interface, the following message is displayed:  
An IP address in this range is already in use by a LIF. Associate the LIF with this subnet?
  - b. When you click **OK**, the existing LIF will be associated with the subnet.

## CLI

### Use the CLI to add or remove IP addresses to or from a subnet

#### About this task

When adding IP addresses, you will receive an error if any service processor or network interfaces are using the IP addresses in the range being added. If you want to associate any manually addressed interfaces with the current subnet, you can set the `-force-update-lif-associations` option to `true`.

When removing IP addresses, you will receive an error if any service processor or network interfaces are using the IP addresses being removed. If you want the interfaces to continue to use the IP addresses after they are removed from the subnet, you can set the `-force-update-lif-associations` option to `true`.

#### Step

Add or remove IP addresses from a subnet:

| If you want to...                 | Use this command...                       |
|-----------------------------------|-------------------------------------------|
| Add IP addresses to a subnet      | <code>network subnet add-ranges</code>    |
| Remove IP addresses from a subnet | <code>network subnet remove-ranges</code> |

For more information about these commands, see the man pages.

The following command adds IP addresses 192.0.2.82 through 192.0.2.85 to subnet sub1:

```
network subnet add-ranges -subnet-name <sub1> -ip-ranges <192.0.2.82-192.0.2.85>
```

The following command removes IP address 198.51.100.9 from subnet sub3:

```
network subnet remove-ranges -subnet-name <sub3> -ip-ranges
<198.51.100.9>
```

If the current range includes 1 through 10 and 20 through 40, and you want to add 11 through 19 and 41 through 50 (basically allowing 1 through 50), you can overlap the existing range of addresses by using the following command. This command adds only the new addresses and does not affect the existing addresses:

```
network subnet add-ranges -subnet-name <sub3> -ip-ranges <198.51.10.1-
198.51.10.50>
```

### Change subnet properties

You can change the subnet address and mask value, gateway address, or range of IP addresses in an existing subnet.

#### About this task

- When modifying IP addresses, you must ensure there are no overlapping IP addresses in the network so that different subnets, or hosts, do not attempt to use the same IP address.
- If you add or change the gateway IP address, the modified gateway is applied to new SVMs when a LIF is created in them using the subnet. A default route to the gateway is created for the SVM if the route does not already exist. You may need to manually add a new route to the SVM when you change the gateway IP address.

The procedure you follow depends on the interface that you use—System Manager or the CLI:

## System Manager

Beginning with ONTAP 9.12.0, you can use System Manager to change subnet properties

### Steps

1. Select **Network > Overview > Subnets**.
2. Select  **Edit** beside the subnet you want to change.
3. Make changes.
4. Save your changes.
  - a. If the IP address or range entered is already used by an interface, the following message is displayed:  
An IP address in this range is already in use by a LIF. Associate the LIF with this subnet?
  - b. When you click **OK**, the existing LIF will be associated with the subnet.

## CLI

Use the CLI to change subnet properties

### Step

Modify subnet properties:

```
network subnet modify -subnet-name <subnet_name> [-ipspace
<ipspace_name>] [-subnet <subnet_address>] [-gateway <gateway_address>]
[-ip-ranges <ip_address_list>] [-force-update-lif-associations <true>]
```

- `subnet_name` is the name of the subnet you want to modify.
- `ipspace` is the name of the IPspace where the subnet resides.
- `subnet` is the new address and mask of the subnet, if applicable; for example, 192.0.2.0/24.
- `gateway` is the new gateway of the subnet, if applicable; for example, 192.0.2.1. Entering "" removes the gateway entry.
- `ip_ranges` is the new list, or range, of IP addresses that will be allocated to the subnet, if applicable. The IP addresses can be individual addresses, a range or IP addresses, or a combination in a comma-separated list. The range specified here replaces the existing IP addresses.
- `force-update-lif-associations` is required when you change the IP address range. You can set the value to `true` for this option when modifying the range of IP addresses. This command fails if any service processor or network interfaces are using the IP addresses in the specified range. Setting this value to `true` associates any manually addressed interfaces with the current subnet and allows the command to succeed.

The following command modifies the gateway IP address of subnet sub3:

```
network subnet modify -subnet-name <sub3> -gateway <192.0.3.1>
```

## Display subnets

You can display the list of IP addresses that are allocated to each subnet within an IPspace. The output also shows the total number of IP addresses that are available in each subnet, and the number of addresses that are currently being used.

The procedure you follow depends on the interface that you use—System Manager or the CLI:

### System Manager

**Beginning with ONTAP 9.12.0, you can use System Manager to display subnets**

#### Steps

1. Select **Network > Overview > Subnets**.
2. View the list of subnets.

### CLI

**Use the CLI to display subnets**

#### Step

Display the list of subnets and the associated IP address ranges that are used in those subnets:

```
network subnet show
```

The following command displays the subnets and the subnet properties:

```
network subnet show

IPspace: Default
Subnet Broadcast Avail/
Name Subnet Domain Gateway Total Ranges
---- ----- ----- ----- -----

sub1 192.0.2.0/24 bcast1 192.0.2.1 5/9 192.0.2.92-
192.0.2.100
sub3 198.51.100.0/24 bcast3 198.51.100.1 3/3
198.51.100.7,198.51.100.9
```

## Delete a subnet

If you no longer need a subnet and want to deallocate the IP addresses that were assigned to the subnet, you can delete it.

The procedure you follow depends on the interface that you use—System Manager or the CLI:

## System Manager

Beginning with ONTAP 9.12.0, you can use System Manager to delete a subnet

### Steps

1. Select **Network > Overview > Subnets**.
2. Select  > **Delete** beside the subnet you want to remove.
3. Save your changes.

### CLI

Use the CLI to delete a subnet

#### About this task

You will receive an error if any service processor or network interfaces are currently using IP addresses in the specified ranges. If you want the interfaces to continue to use the IP addresses even after the subnet is deleted, you can set the `-force-update-lif-associations` option to true to remove the subnet's association with the LIFs.

#### Step

Delete a subnet:

```
network subnet delete -subnet-name subnet_name [-ipspace ipspace_name] [-force-update-lif-associations true]
```

The following command deletes subnet sub1 in IPspace ipspace1:

```
network subnet delete -subnet-name sub1 -ipspace ipspace1
```

## Configure LIFs (cluster administrators only)

### Overview

A LIF (logical interface) represents a network access point to a node in the cluster. You can configure LIFs on ports over which the cluster sends and receives communications over the network.

A cluster administrator can create, view, modify, migrate, revert, or delete LIFs. An SVM administrator can only view the LIFs associated with the SVM.

A LIF is an IP address or WWPN with associated characteristics, such as a service policy, a home port, a home node, a list of ports to fail over to, and a firewall policy. You can configure LIFs on ports over which the cluster sends and receives communications over the network.

Beginning with ONTAP 9.10.1, firewall policies are deprecated and wholly replaced with LIF service policies. For more information, see [Configure firewall policies for LIFs](#).

LIFs can be hosted on the following ports:

- Physical ports that are not part of interface groups

- Interface groups
- VLANs
- Physical ports or interface groups that host VLANs
- Virtual IP (VIP) ports

Beginning with ONTAP 9.5, VIP LIFs are supported and are hosted on VIP ports.

While configuring SAN protocols such as FC on a LIF, it will be associated with a WWPN.

## [SAN administration](#)

The following figure illustrates the port hierarchy in an ONTAP system:

## LIF compatibility with port types

LIFs can have different characteristics to support different port types.

When intercluster and management LIFs are configured in the same subnet, the management traffic might be blocked by an external firewall and the AutoSupport and NTP connections might fail. You can recover the system by running the `network interface modify -vserver vserver name -lif intercluster LIF -status-admin up|down` command to toggle the intercluster LIF. However, you should set the intercluster LIF and management LIF in different subnets to avoid this issue.

| LIF                    | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
|------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Data LIF               | A LIF that is associated with a storage virtual machine (SVM) and is used for communicating with clients.<br>You can have multiple data LIFs on a port. These interfaces can migrate or fail over throughout the cluster. You can modify a data LIF to serve as an SVM management LIF by modifying its firewall policy to mgmt.<br><br>Sessions established to NIS, LDAP, Active Directory, WINS, and DNS servers use data LIFs.                                                                                                    |
| Cluster LIF            | A LIF that is used to carry intracluster traffic between nodes in a cluster. Cluster LIFs must always be created on cluster ports.<br><br>Cluster LIFs can fail over between cluster ports on the same node, but they cannot be migrated or failed over to a remote node. When a new node joins a cluster, IP addresses are generated automatically. However, if you want to assign IP addresses manually to the cluster LIFs, you must ensure that the new IP addresses are in the same subnet range as the existing cluster LIFs. |
| Cluster management LIF | LIF that provides a single management interface for the entire cluster.<br><br>A cluster management LIF can fail over to any node in the cluster. It cannot fail over to cluster or intercluster ports                                                                                                                                                                                                                                                                                                                              |
| Intercluster LIF       | A LIF that is used for cross-cluster communication, backup, and replication. You must create an intercluster LIF on each node in the cluster before a cluster peering relationship can be established.<br><br>These LIFs can only fail over to ports in the same node. They cannot be migrated or failed over to another node in the cluster.                                                                                                                                                                                       |
| Node management LIF    | A LIF that provides a dedicated IP address for managing a particular node in a cluster. Node management LIFs are created at the time of creating or joining the cluster. These LIFs are used for system maintenance, for example, when a node becomes inaccessible from the cluster.                                                                                                                                                                                                                                                |
| VIP LIF                | A VIP LIF is any data LIF created on a VIP port. To learn more, see <a href="#">Configure virtual IP (VIP) LIFs</a> .                                                                                                                                                                                                                                                                                                                                                                                                               |

## LIF roles in ONTAP 9.5 and earlier

LIFs with different roles have different characteristics. A LIF role determines the kind of traffic that is supported over the interface, along with the failover rules that apply, the

firewall restrictions that are in place, the security, the load balancing, and the routing behavior for each LIF. A LIF can have any one of the following roles: cluster, cluster management, data, intercluster, node management, and undef (undefined). The undef role is used for BGP LIFs.

Beginning with ONTAP 9.6, LIF roles are deprecated. You should specify service policies for LIFs instead of a role. It is not necessary to specify a LIF role when creating a LIF with a service policy.

#### LIF security

|                            | Data LIF         | Cluster LIF     | Node management LIF | Cluster management LIF | Intercluster LIF |
|----------------------------|------------------|-----------------|---------------------|------------------------|------------------|
| Require private IP subnet? | No               | Yes             | No                  | No                     | No               |
| Require secure network?    | No               | Yes             | No                  | No                     | Yes              |
| Default firewall policy    | Very restrictive | Completely open | Medium              | Medium                 | Very restrictive |
| Is firewall customizable?  | Yes              | No              | Yes                 | Yes                    | Yes              |

#### LIF failover

|                  | Data LIF                                                                                                  | Cluster LIF                                                                 | Node management LIF                                                         | Cluster management LIF              | Intercluster LIF                                                            |
|------------------|-----------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------|-----------------------------------------------------------------------------|-------------------------------------|-----------------------------------------------------------------------------|
| Default behavior | Only those ports in the same failover group that are on the LIF's home node and on a non-SFO partner node | Only those ports in the same failover group that are on the LIF's home node | Only those ports in the same failover group that are on the LIF's home node | Any port in the same failover group | Only those ports in the same failover group that are on the LIF's home node |
| Is customizable? | Yes                                                                                                       | No                                                                          | Yes                                                                         | Yes                                 | Yes                                                                         |

#### LIF routing

|                                 | Data LIF                                                     | Cluster LIF | Node management LIF                                                           | Cluster management LIF                                  | Intercluster LIF                                          |
|---------------------------------|--------------------------------------------------------------|-------------|-------------------------------------------------------------------------------|---------------------------------------------------------|-----------------------------------------------------------|
| When is a default route needed? | When clients or domain controller are on different IP subnet | Never       | When any of the primary traffic types require access to a different IP subnet | When administrator is connecting from another IP subnet | When other intercluster LIFs are on a different IP subnet |

|                                                          |                                                                                                                                                                            |       |      |      |                                                                                    |
|----------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------|------|------|------------------------------------------------------------------------------------|
| When is a static route to a specific IP subnet needed?   | Rare                                                                                                                                                                       | Never | Rare | Rare | When nodes of another cluster have their intercluster LIFs in different IP subnets |
| When is a static host route to a specific server needed? | To have one of the traffic types listed under node management LIF, go through a data LIF rather than a node management LIF. This requires a corresponding firewall change. | Never | Rare | Rare | Rare                                                                               |

#### LIF rebalancing

|                         | Data LIF | Cluster LIF | Node management LIF | Cluster management LIF | Intercluster LIF |
|-------------------------|----------|-------------|---------------------|------------------------|------------------|
| DNS: use as DNS server? | Yes      | No          | No                  | No                     | No               |
| DNS: export as zone?    | Yes      | No          | No                  | No                     | No               |

#### LIF primary traffic types

|                       | Data LIF                                                                                                      | Cluster LIF  | Node management LIF                                                                                  | Cluster management LIF   | Intercluster LIF          |
|-----------------------|---------------------------------------------------------------------------------------------------------------|--------------|------------------------------------------------------------------------------------------------------|--------------------------|---------------------------|
| Primary traffic types | NFS server, CIFS server, NIS client, Active Directory, LDAP, WINS, DNS client and server, iSCSI and FC server | Intracluster | SSH server, HTTPS server, NTP client, SNMP, AutoSupport client, DNS client, loading software updates | SSH server, HTTPS server | Cross-cluster replication |

#### LIFs and service policies in ONTAP 9.6 and later

You can assign service policies (instead of LIF roles or firewall policies) to LIFs that determine the kind of traffic that is supported for the LIFs. Service policies define a collection of network services supported by a LIF. ONTAP provides a set of built-in service policies that can be associated with a LIF.

You can display service policies and their details using the following command:

```
network interface service-policy show
```

#### Service policies for system SVMs

The admin SVM and any system SVM contain service policies that can be used for LIFs in that SVM, including management and intercluster LIFs. These policies are automatically created by the system when an IPspace is created.

The following table lists the built-in policies for LIFs in system SVMs as of ONTAP 9.12.1. For other releases, display the service policies and their details using the following command:

```
network interface service-policy show
```

| Policy                 | Included services                                                                                                                                                                                                                                        | Equivalent role            | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
|------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| default-intercluster   | intercluster-core, management-https                                                                                                                                                                                                                      | intercluster               | Used by LIFs carrying intercluster traffic.<br>Note: Service intercluster-core is available from ONTAP 9.5 with the name net-intercluster service policy.                                                                                                                                                                                                                                                                                                                   |
| default-route-announce | management-bgp                                                                                                                                                                                                                                           | -                          | Used by LIFs carrying BGP peer connections<br>Note: Available from ONTAP 9.5 with the name net-route-announce service policy.                                                                                                                                                                                                                                                                                                                                               |
| default-management     | management-core, management-https, management-http, management-ssh, management-autosupport, management-ems, management-dns-client, management-ad-client, management-ldap-client, management-nis-client, management-ntp-client, management-log-forwarding | node-mgmt, or cluster-mgmt | Use this system scoped management policy to create node- and cluster-scoped management LIFs owned by a system SVM. These LIFs can be used for outbound connections to DNS, AD, LDAP, or NIS servers as well as some additional connections to support applications that run on behalf of the entire system.<br>Beginning in ONTAP 9.12.1, you can use the management-log-forwarding service to control which LIFs are used to forward audit logs to a remote syslog server. |

The following table lists the services that LIFs can use on a system SVM as of ONTAP 9.11.1:

| Service           | Failover limitations | Description                |
|-------------------|----------------------|----------------------------|
| intercluster-core | home-node-only       | Core intercluster services |
| management-core   | -                    | Core management services   |

|                           |                |                                                                          |
|---------------------------|----------------|--------------------------------------------------------------------------|
| management-ssh            | -              | Services for SSH management access                                       |
| management-http           | -              | Services for HTTP management access                                      |
| management-https          | -              | Services for HTTPS management access                                     |
| management-autosupport    | -              | Services related to posting AutoSupport payloads                         |
| management-bgp            | home-port-only | Services related to BGP peer interactions                                |
| backup-ndmp-control       | -              | Services for NDMP backup controls                                        |
| management-ems            | -              | Services for management messaging access                                 |
| management-ntp-client     | -              | Introduced in ONTAP 9.10.1.<br>Services for NTP client access.           |
| management-ntp-server     | -              | Introduced in ONTAP 9.11.1.<br>Services for NTP server management access |
| management-portmap        | -              | Services for portmap management                                          |
| management-rsh-server     | -              | Services for rsh server management                                       |
| management-snmp-server    | -              | Services for SNMP server management                                      |
| management-telnet-server  | -              | Services for telnet server management                                    |
| management-log-forwarding | -              | Introduced in ONTAP 9.12.1.<br>Services for audit log forwarding         |

#### Service policies for data SVMs

All data SVMs contain service policies that can be used by LIFs in that SVM.

The following table lists the built-in policies for LIFs in data SVMs as of ONTAP 9.11.1. For other releases, display the service policies and their details using the following command:

```
network interface service-policy show
```

| Policy | Included services | Equivalent data protocol | Description |
|--------|-------------------|--------------------------|-------------|
|        |                   |                          |             |

|                       |                                                                                                                                                                       |                   |                                                                                                                                                                                                                                                                                                                                                                                   |
|-----------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| default-management    | management-https, management-http, management-ssh, management-dns-client, management-ad-client, management-ldap-client, management-nis-client                         | none              | Use this SVM-scoped management policy to create SVM management LIFs owned by a data SVM. These LIFs can be used to provide SSH or HTTPS access to SVM administrators. When necessary, these LIFs can be used for outbound connections to an external DNS, AD, LDAP, or NIS servers.                                                                                               |
| default-data-blocks   | data-core, data-iscsi                                                                                                                                                 | iscsi             | Used by LIFs carrying block-oriented SAN data traffic. Starting in ONTAP 9.10.1, the "default-data-blocks" policy is deprecated. Use the "default-data-iscsi" service policy instead.                                                                                                                                                                                             |
| default-data-files    | data-fpolicy-client, data-dns-server, data-flexcache, data-cifs, data-nfs, management-dns-client, management-ad-client, management-ldap-client, management-nis-client | nfs, cifs, fcache | Use the default-data-files policy to create NAS LIFs supporting file-based data protocols. Sometimes there is only one LIF present in the SVM, therefore this policy allows the LIF to be used for outbound connections to an external DNS, AD, LDAP, or NIS server. You can remove these services from this policy if you prefer these connections utilize only management LIFs. |
| default-data-iscsi    | data-core, data-iscsi                                                                                                                                                 | iscsi             | Used by LIFs carrying iSCSI data traffic.                                                                                                                                                                                                                                                                                                                                         |
| default-data-nvme-tcp | data-core, data-nvme-tcp                                                                                                                                              | nvme-tcp          | Used by LIFs carrying NVMe/TCP data traffic.                                                                                                                                                                                                                                                                                                                                      |

The following table lists the services that can be used on a data SVM along with any restrictions each service imposes on a LIF's failover policy as of ONTAP 9.11.1:

| Service                | Failover restrictions | Description                                                              |
|------------------------|-----------------------|--------------------------------------------------------------------------|
| management-ssh         | -                     | Services for SSH management access                                       |
| management-http        | -                     | Introduced in ONTAP 9.10.1<br>Services for HTTP management access        |
| management-https       | -                     | Services for HTTPS management access                                     |
| management-portmap     | -                     | Services for portmap management access                                   |
| management-snmp-server | -                     | Introduced in ONTAP 9.10.1<br>Services for SNMP server management access |

|                     |                |                                                                 |
|---------------------|----------------|-----------------------------------------------------------------|
| data-core           | -              | Core data services                                              |
| data-nfs            | -              | NFS data service                                                |
| data-cifs           | -              | CIFS data service                                               |
| data-flexcache      | -              | FlexCache data service                                          |
| data-iscsi          | home-port-only | iSCSI data service                                              |
| backup-ndmp-control | -              | Introduced in ONTAP 9.10.1<br>Backup NDMP controls data service |
| data-dns-server     | -              | Introduced in ONTAP 9.10.1<br>DNS server data service           |
| data-fpolicy-client | -              | File-screening policy data service                              |
| data-nvme-tcp       | home-port-only | Introduced in ONTAP 9.10.1<br>NVMe TCP data service             |
| data-s3-server      | -              | Simple Storage Service (S3) server data service                 |

You should be aware of how the service policies are assigned to the LIFs in data SVMs:

- If a data SVM is created with a list of data services, the built-in "default-data-files" and "default-data-blocks" service policies in that SVM are created using the specified services.
- If a data SVM is created without specifying a list of data services, the built-in "default-data-files" and "default-data-blocks" service policies in that SVM are created using a default list of data services.

The default data services list includes the iSCSI, NFS, NVMe, SMB, and FlexCache services.

- When a LIF is created with a list of data protocols, a service policy equivalent to the specified data protocols is assigned to the LIF.
- If an equivalent service policy does not exist, a custom service policy is created.
- When a LIF is created without a service policy or list of data protocols, the default-data-files service policy is assigned to the LIF by default.

#### Data-core service

The data-core service allows components that previously used LIFs with the data role to work as expected on clusters that have been upgraded to manage LIFs using service policies instead of LIF roles (which are deprecated in ONTAP 9.6).

Specifying data-core as a service does not open any ports in the firewall, but the service should be included in any service policy in a data SVM. For example, the default-data-files service policy contains the following services by default:

- data-core
- data-nfs
- data-cifs
- data-flexcache

The data-core service should be included in the policy to ensure all applications using the LIF work as expected, but the other three services can be removed, if desired.

#### **Client-side LIF service**

Beginning with ONTAP 9.10.1, ONTAP provides client-side LIF services for multiple applications. These services provide control over which LIFs are used for outbound connections on behalf of each application.

The following new services give administrators control over which LIFs are used as source addresses for certain applications.

| Service                | SVM restrictions | Description                                                                                                                    |
|------------------------|------------------|--------------------------------------------------------------------------------------------------------------------------------|
| management-ad-client   | -                | Beginning with ONTAP 9.11.1, ONTAP provides Active Directory client service for outbound connections to an external AD server. |
| management-dns-client  | -                | Beginning with ONTAP 9.11.1, ONTAP provides DNS client service for outbound connections to an external DNS server.             |
| management-ldap-client | -                | Beginning with ONTAP 9.11.1, ONTAP provides LDAP client service for outbound connections to an external LDAP server.           |
| management-nis-client  | -                | Beginning with ONTAP 9.11.1, ONTAP provides NIS client service for outbound connections to an external NIS server.             |
| management-ntp-client  | system-only      | Beginning with ONTAP 9.10.1, ONTAP provides NTP client service for outbound connections to an external NTP server.             |
| data-fpolicy-client    | data-only        | Beginning with ONTAP 9.8, ONTAP provides client service for outbound FPolicy connections.                                      |

Each of the new services are automatically included in some of the built-in service policies, but administrators can remove them from the built-in policies or add them to custom policies to control which LIFs are used for outbound connections on behalf of each application.

#### **Configure LIF service policies**

You can configure LIF service policies to identify a single service or a list of services that will use a LIF.

## Create a service policy for LIFs

You can create a service policy for LIFs. You can assign a service policy to one or more LIFs; thereby allowing the LIF to carry traffic for a single service or a list of services.

You need advanced privileges to run the `network interface service-policy create` command.

### About this task

Built-in services and service policies are available for managing data and management traffic on both data and system SVMs. Most use cases are satisfied using a built-in service policy rather than creating a custom service policy.

You can modify these built-in service policies, if required.

### Steps

1. View the services that are available in the cluster:

```
network interface service show
```

Services represent the applications accessed by a LIF as well as the applications served by the cluster. Each service includes zero or more TCP and UDP ports on which the application is listening.

The following additional data and management services are available:

```
cluster1::> network interface service show

Service Protocol:Ports

cluster-core -
data-cifs -
data-core -
data-flexcache -
data-iscsi -
data-nfs -
intercluster-core tcp:11104-11105
management-autosupport -
management-bgp tcp:179
management-core -
management-https tcp:443
management-ssh tcp:22
12 entries were displayed.
```

2. View the service policies that exist in the cluster:

```

cluster1::> network interface service-policy show

Vserver Policy Service: Allowed Addresses
----- -----
----- -----
cluster1
 default-intercluster intercluster-core: 0.0.0.0/0
 management-https: 0.0.0.0/0

 default-management management-core: 0.0.0.0/0
 management-autosupport: 0.0.0.0/0
 management-ssh: 0.0.0.0/0
 management-https: 0.0.0.0/0

 default-route-announce management-bgp: 0.0.0.0/0

Cluster
 default-cluster cluster-core: 0.0.0.0/0

vs0
 default-data-blocks data-core: 0.0.0.0/0
 data-iscsi: 0.0.0.0/0

 default-data-files data-core: 0.0.0.0/0
 data-nfs: 0.0.0.0/0
 data-cifs: 0.0.0.0/0
 data-flexcache: 0.0.0.0/0

 default-management data-core: 0.0.0.0/0
 management-ssh: 0.0.0.0/0
 management-https: 0.0.0.0/0

7 entries were displayed.

```

### 3. Create a service policy:

```

cluster1::> set -privilege advanced
Warning: These advanced commands are potentially dangerous; use them
only when directed to do so by technical support.
Do you wish to continue? (y or n): y

cluster1::> network interface service-policy create -vserver <svm_name>
-policies <service_policy_name> -services <service_name> -allowed
-addresses <IP_address/mask,...>

```

- "service\_name" specifies a list of services that should be included in the policy.
- "IP\_address/mask" specifies the list of subnet masks for addresses that are allowed to access the services in the service policy. By default, all specified services are added with a default allowed address list of 0.0.0.0/0, which allows traffic from all subnets. When a non-default allowed address list is provided, LIFs using the policy are configured to block all requests with a source address that does not match any of the specified masks.

The following example shows how to create a data service policy, *svm1\_data\_policy*, for an SVM that includes *NFS* and *SMB* services:

```
cluster1::> set -privilege advanced
Warning: These advanced commands are potentially dangerous; use them
only when directed to do so by technical support.
Do you wish to continue? (y or n): y

cluster1::> network interface service-policy create -vserver svm1
-priority svm1_data_policy -services data-nfs,data-cifs,data-core
```

The following example shows how to create an intercluster service policy:

```
cluster1::> set -privilege advanced
Warning: These advanced commands are potentially dangerous; use them
only when directed to do so by technical support.
Do you wish to continue? (y or n): y

cluster1::> network interface service-policy create -vserver cluster1
-priority intercluster1 -services intercluster-core
```

#### 4. Verify that the service policy is created.

```
cluster1::> network interface service-policy show
```

The following output shows the service policies that are available:

```

cluster1::> network interface service-policy show

Vserver Policy Service: Allowed Addresses
----- -----
----- -----
cluster1
 default-intercluster intercluster-core: 0.0.0.0/0
 management-https: 0.0.0.0/0

 intercluster1 intercluster-core: 0.0.0.0/0

 default-management management-core: 0.0.0.0/0
 management-autosupport: 0.0.0.0/0
 management-ssh: 0.0.0.0/0
 management-https: 0.0.0.0/0

 default-route-announce management-bgp: 0.0.0.0/0

Cluster
 default-cluster cluster-core: 0.0.0.0/0

vs0
 default-data-blocks data-core: 0.0.0.0/0
 data-iscsi: 0.0.0.0/0

 default-data-files data-core: 0.0.0.0/0
 data-nfs: 0.0.0.0/0
 data-cifs: 0.0.0.0/0
 data-flexcache: 0.0.0.0/0

 default-management data-core: 0.0.0.0/0
 management-ssh: 0.0.0.0/0
 management-https: 0.0.0.0/0

 svm1_data_policy data-core: 0.0.0.0/0
 data-nfs: 0.0.0.0/0
 data-cifs: 0.0.0.0/0

9 entries were displayed.

```

### After you finish

Assign the service policy to a LIF either at the time of creation or by modifying an existing LIF.

## Assign a service policy to a LIF

You can assign a service policy to a LIF either at the time of creating the LIF or by modifying the LIF. A service policy defines the list of services that can be used with the LIF.

### About this task

You can assign service policies for LIFs in the admin and data SVMs.

### Step

Depending on when you want to assign the service policy to a LIF, perform one of the following actions:

| If you are...   | Assign the service policy...                                                                                                                                                                                              |
|-----------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Creating a LIF  | network interface create -vserver svm_name -lif <lif_name> -home-node <node_name> -home-port <port_name> {(-address <IP_address> -netmask <IP_address>) -subnet-name <subnet_name>} -service-policy <service_policy_name> |
| Modifying a LIF | network interface modify -vserver <svm_name> -lif <lif_name> -service-policy <service_policy_name>                                                                                                                        |

When you specify a service policy for a LIF, you need not specify the data protocol and role for the LIF. Creating LIFs by specifying the role and data protocols is also supported.

A service policy can only be used by LIFs in the same SVM that you specified when creating the service policy.

### Examples

The following example shows how to modify the service policy of a LIF to use the default- management service policy:

```
cluster1::> network interface modify -vserver cluster1 -lif lif1 -service -policy default-management
```

### Commands for managing LIF service policies

Use the `network interface service-policy` commands to manage LIF service policies.

| If you want to...                                                                            | Use this command...                                       |
|----------------------------------------------------------------------------------------------|-----------------------------------------------------------|
| Create a service policy (advanced privileges required)                                       | <code>network interface service-policy create</code>      |
| Add an additional service entry to an existing service policy (advanced privileges required) | <code>network interface service-policy add-service</code> |
| Clone an existing service policy (advanced privileges required)                              | <code>network interface service-policy clone</code>       |

|                                                                                           |                                                   |
|-------------------------------------------------------------------------------------------|---------------------------------------------------|
| Modify a service entry in an existing service policy<br>(advanced privileges required)    | network interface service-policy modify-service   |
| Remove a service entry from an existing service policy<br>(advanced privileges required)  | network interface service-policy remove-service   |
| Rename an existing service policy (advanced privileges required)                          | network interface service-policy rename           |
| Delete an existing service policy (advanced privileges required)                          | network interface service-policy delete           |
| Restore a built-in service-policy to its original state<br>(advanced privileges required) | network interface service-policy restore-defaults |
| Display existing service policies                                                         | network interface service-policy show             |

### Create a LIF (network interface)

A LIF (network interface) is an IP address associated with a physical or logical port. If there is a component failure, a LIF can fail over to or be migrated to a different physical port, thereby continuing to communicate with the network.

#### Before you begin

- The underlying physical or logical network port must have been configured to the administrative up status.
- If you are planning to use a subnet name to allocate the IP address and network mask value for a LIF, the subnet must already exist.

Subnets contain a pool of IP addresses that belong to the same layer 3 subnet. They are created using System Manager or the `network subnet create` command.

- The mechanism for specifying the type of traffic handled by a LIF has changed. For ONTAP 9.5 and earlier, LIFs used roles to specify the type of traffic it would handle. Beginning with ONTAP 9.6, LIFs use service policies to specify the type of traffic it would handle.

#### About this task

- You cannot assign NAS and SAN protocols to the same LIF.

The supported protocols are SMB, NFS, FlexCache, iSCSI, and FC; iSCSI and FC cannot be combined with other protocols. However, NAS and Ethernet-based SAN protocols can be present on the same physical port.

- You can create both IPv4 and IPv6 LIFs on the same network port.
- All the name mapping and host-name resolution services used by an SVM, such as DNS, NIS, LDAP, and Active Directory, must be reachable from at least one LIF handling data traffic of the SVM.
- A LIF handling intracluster traffic between nodes should not be on the same subnet as a LIF handling management traffic or a LIF handling data traffic.

- Creating a LIF that does not have a valid failover target results in a warning message.
- If you have a large number of LIFs in your cluster, you can verify the LIF capacity supported on the cluster:
  - System Manager: Beginning with ONTAP 9.12.0, view the throughput on the Network Interface grid.
  - CLI: Use the `network interface capacity show` command and the LIF capacity supported on each node by using the `network interface capacity details show` command (at the advanced privilege level).
- Beginning with ONTAP 9.7, if other LIFs already exist for the SVM in the same subnet, you do not need to specify the home port of the LIF. ONTAP automatically chooses a random port on the specified home node in the same broadcast domain as the other LIFs already configured in the same subnet.

Beginning with ONTAP 9.4, FC-NVMe is supported. If you are creating an FC-NVMe LIF you should be aware of the following:

- The NVMe protocol must be supported by the FC adapter on which the LIF is created.
- FC-NVMe can be the only data protocol on data LIFs.
- One LIF handling management traffic must be configured for every storage virtual machine (SVM) supporting SAN.
- NVMe LIFs and namespaces must be hosted on the same node.
- Only one NVMe LIF handling data traffic can be configured per SVM.
- When you create a network interface with a subnet, ONTAP automatically selects an available IP address from the selected subnet and assigns it to the network interface. You can change the subnet if there is more than one subnet, but you cannot change the IP address.
- When you create (add) an SVM, for a network interface, you cannot specify an IP address that is in the range of an existing subnet. You will receive a subnet conflict error. This issue occurs in other workflows for a network interface, such as creating or modifying inter-cluster network interfaces in SVM settings or cluster settings.
- Beginning with ONTAP 9.10.1, the `network interface` CLI commands include an `-rdma-protocols` parameter for NFS over RDMA configurations. Creating network interfaces for NFS over RDMA configurations is supported in System Manager beginning in ONTAP 9.12.1. For more information, see [Configure LIFs for NFS over RDMA](#).
- Beginning with ONTAP 9.11.1, the iSCSI LIF failover feature is available on All SAN Array (ASA) platforms.

iSCSI LIF failover is automatically enabled (the failover policy is set to `sfo-partner-only` and the auto-revert value is set to `true`) on newly created iSCSI LIFs if no iSCSI LIFs exist in the specified SVM or if all existing iSCSI LIFs in the specified SVM are already enabled with iSCSI LIF failover.

If after you upgrade to ONTAP 9.11.1 or later, you have existing iSCSI LIFs in an SVM that have not been enabled with the iSCSI LIF failover feature and you create new iSCSI LIFs in the same SVM, the new iSCSI LIFs assume the same failover policy (`disabled`) of the existing iSCSI LIFs in the SVM.

### [iSCSI LIF failover for ASA platforms](#)

Beginning with ONTAP 9.12.0, the procedure you follow depends on the interface that you use—System Manager or the CLI:

## **System Manager**

### **Use System Manager to add a network interface**

#### **Steps**

1. Select **Network > Overview > Network Interfaces**.
2. Select **+ Add**.
3. Select one of the following interface roles:
  - a. Data
  - b. Intercluster
  - c. SVM Management
4. Select the protocol:
  - a. SMB/CIFS and NFS
  - b. iSCSI
  - c. FC
  - d. NVMe/FC
  - e. NVMe/TCP
5. Name the LIF or accept the name generated from your previous selections.
6. Accept the home node or use the drop-down to select one.
7. If at least one subnet is configured in the IPspace of the selected SVM, the subnet drop-down is displayed.
  - a. If you select a subnet, choose it from the drop-down.
  - b. If you proceed without a subnet, the broadcast domain drop-down is displayed:
    - i. Specify the IP address. If the IP address is in use, a warning message will display.
    - ii. Specify a subnet mask.
8. Select the home port from the broadcast domain, either automatically (recommended) or by selecting one from the drop-down menu. The Home port control is displayed based on the broadcast domain or subnet selection.
9. Save the network interface.

## **CLI**

### **Use the CLI to create a LIF**

#### **Steps**

1. Create a LIF:

```
network interface create -vserver _SVM_name_ -lif _lif_name_
-service-policy _service_policy_name_ -home-node _node_name_ -home
-port port_name {-address _IP_address_ - netmask _Netmask_value_ |
-subnet-name _subnet_name_} -firewall- policy _policy_ -auto-revert
{true|false}
```

- `-home-node` is the node to which the LIF returns when the `network interface revert` command is run on the LIF.

You can also specify whether the LIF should automatically revert to the home-node and home-port with the `-auto-revert` option.

- `-home-port` is the physical or logical port to which the LIF returns when the `network interface revert` command is run on the LIF.
- You can specify an IP address with the `-address` and `-netmask` options, or you enable allocation from a subnet with the `-subnet_name` option.
- When using a subnet to supply the IP address and network mask, if the subnet was defined with a gateway, a default route to that gateway is added automatically to the SVM when a LIF is created using that subnet.
- If you assign IP addresses manually (without using a subnet), you might need to configure a default route to a gateway if there are clients or domain controllers on a different IP subnet. The `network route create` man page contains information about creating a static route within an SVM.
- `-auto-revert` enables you to specify whether a data LIF is automatically reverted to its home node under circumstances such as startup, changes to the status of the management database, or when the network connection is made. The default setting is `false`, but you can set it to `true` depending on network management policies in your environment.
- `-service-policy` Beginning with ONTAP 9.5, you can assign a service policy for the LIF with the `-service-policy` option.  
When a service policy is specified for a LIF, the policy is used to construct a default role, failover policy, and data protocol list for the LIF. In ONTAP 9.5, service policies are supported only for intercluster and BGP peer services. In ONTAP 9.6, you can create service policies for several data and management services.
- `-data-protocol` enables you to create a LIF that supports the FCP or NVMe/FC protocols. This option is not required when creating an IP LIF.

## 2. Optional: Assign an IPv6 address in the `-address` option:

- a. Use the `network ndp prefix show` command to view the list of RA prefixes learned on various interfaces.

The `network ndp prefix show` command is available at the advanced privilege level.

- b. Use the format `prefix::id` to construct the IPv6 address manually.

`prefix` is the prefix learned on various interfaces.

For deriving the `id`, choose a random 64-bit hexadecimal number.

## 3. Verify that the LIF was created by using the `network interface show` command.

## 4. Verify that the configured IP address is reachable:

| To verify an... | Use...                     |
|-----------------|----------------------------|
| IPv4 address    | <code>network ping</code>  |
| IPv6 address    | <code>network ping6</code> |

## Examples

The following command creates a LIF and specifies the IP address and network mask values using the `-address` and `-netmask` parameters:

```
network interface create -vserver vs1.example.com -lif datalif1
-service-policy default-data-files -home-node node-4 -home-port e1c
-address 192.0.2.145 -netmask 255.255.255.0 -auto-revert true
```

The following command creates a LIF and assigns IP address and network mask values from the specified subnet (named `client1_sub`):

```
network interface create -vserver vs3.example.com -lif datalif3
-service-policy default-data-files -home-node node-3 -home-port e1c
-subnet-name client1_sub - auto-revert true
```

The following command creates an NVMe/FC LIF and specifies the `nvme-fc` data protocol:

```
network interface create -vserver vs1.example.com -lif datalif1 -data
-protocol nvme-fc -home-node node-4 -home-port 1c -address 192.0.2.145
-netmask 255.255.255.0 -auto-revert true
```

## More information

[Modify a LIF](#)

[Configure LIFs for NFS over RDMA](#)

## Modify a LIF

You can modify a LIF by changing the attributes, such as home node or current node, administrative status, IP address, netmask, failover policy, firewall policy, and service policy. You can also change the address family of a LIF from IPv4 to IPv6.

### About this task

- When modifying a LIF's administrative status to down, any outstanding NFSv4 locks are held until the LIF's administrative status is returned to up.

To avoid lock conflicts that can occur when other LIFs attempt to access the locked files, you must move the NFSv4 clients to a different LIF before setting the administrative status to down.

- You cannot modify the data protocols used by an FC LIF. However, you can modify the services assigned to a service policy or change the service policy assigned to an IP LIF.

To modify the data protocols used by a FC LIF, you must delete and re-create the LIF. To make service policy changes to an IP LIF, there is a brief outage while the updates occur.

- You cannot modify either the home node or the current node of a node-scoped management LIF.

- When using a subnet to change the IP address and network mask value for a LIF, an IP address is allocated from the specified subnet; if the LIF's previous IP address is from a different subnet, the IP address is returned to that subnet.
- To modify the address family of a LIF from IPv4 to IPv6, you must use the colon notation for the IPv6 address and add a new value for the `-netmask-length` parameter.
- You cannot modify the auto-configured link-local IPv6 addresses.
- Modification of a LIF that results in the LIF having no valid failover target results in a warning message.

If a LIF that does not have a valid failover target attempts to fail over, an outage might occur.

- Beginning with ONTAP 9.5, you can modify the service policy associated with a LIF.

In ONTAP 9.5, service policies are supported only for intercluster and BGP peer services. In ONTAP 9.6, you can create service policies for several data and management services.

- Beginning with ONTAP 9.11.1, the iSCSI LIF failover feature is available on All SAN Array (ASA) platforms.

For pre-existing iSCSI LIFs, meaning LIFs created prior to upgrading to 9.11.1 or later, you can modify the failover policy to enable the iSCSI LIF failover feature.

#### [iSCSI LIF failover for ASA platforms](#)

The procedure you follow depends on the interface that you use—System Manager or the CLI:

## System Manager

Beginning with ONTAP 9.12.0, you can use System Manager to edit a network interface

### Steps

1. Select **Network > Overview > Network Interfaces**.
2. Select  **Edit** beside the network interface you want to change.
3. Change one or more of the network interface settings. For details, see [Create a LIF](#).
4. Save your changes.

## CLI

### Use the CLI to modify a LIF

#### Steps

1. Modify a LIF's attributes by using the `network interface modify` command.

The following example shows how to modify the IP address and network mask of LIF `datalif2` using an IP address and the network mask value from subnet `client1_sub`:

```
network interface modify -vserver vs1 -lif datalif2 -subnet-name
client1_sub
```

The following example shows how to modify the service policy of a LIF.

```
network interface modify -vserver siteA -lif node1_inter1 -service
-policy example
```

2. Verify that the IP addresses are reachable.

| If you are using... | Then use...                |
|---------------------|----------------------------|
| IPv4 addresses      | <code>network ping</code>  |
| IPv6 addresses      | <code>network ping6</code> |

## Migrate a LIF

You might have to migrate a LIF to a different port on the same node or a different node within the cluster, if the port is either faulty or requires maintenance. Migrating a LIF is similar to LIF failover, but LIF migration is a manual operation, while LIF failover is the automatic migration of a LIF in response to a link failure on the LIF's current network port.

### Before you begin

- A failover group must have been configured for the LIFs.

- The destination node and ports must be operational and must be able to access the same network as the source port.

## About this task

- BGP LIFs reside on the home-port and cannot be migrated to any other node or port.
- You must migrate LIFs hosted on the ports belonging to a NIC to other ports in the cluster, before removing the NIC from the node.
- You must execute the command for migrating a cluster LIF from the node where the cluster LIF is hosted.
- A node-scoped LIF, such as a node-scoped management LIF, cluster LIF, intercluster LIF, cannot be migrated to a remote node.
- When an NFSv4 LIF is migrated between nodes, a delay of up to 45 seconds results before the LIF is available on a new port.

To work around this problem, use NFSv4.1 where no delay is encountered.

- You can migrate iSCSI LIFs on All SAN Array (ASA) platforms running ONTAP 9.11.1 or later.

Migrating iSCSI LIFs is limited to ports on the home-node or the HA partner.

You can also use System Manager to migrate iSCSI LIFs.

### [iSCSI LIF failover for ASA platforms](#)

- If your platform is not an All SAN Array (ASA) platform running ONTAP version 9.11.1 or later, you cannot migrate iSCSI LIFs from one node to another node.

To work around this restriction, you must create an iSCSI LIF on the destination node. Learn about [creating iSCSI LIFs](#).

- If you want to migrate a LIF (network interface) for NFS over RDMA, you must ensure the destination port is RoCE capable. You must be running ONTAP 9.10.1 or later to migrate a LIF with the CLI, or ONTAP 9.12.1 to migrate using System Manager. In System Manager, once you have selected your RoCE capable destination-port, you must check the box next to **Use RoCE ports** to complete the migration successfully. Learn more about [configuring LIFs for NFS over RDMA](#).
- VMware VAAI copy offload operations fail when you migrate the source or the destination LIF. Learn about [copy off-load](#):
  - [NFS environments](#)
  - [SAN environments](#)

The procedure you follow depends on the interface that you use—System Manager or the CLI:

## System Manager

### Use System Manager to migrate a network interface

#### Steps

1. Select **Network > Overview > Network Interfaces**.
2. Select > **Migrate** beside the network interface you want to change.
3. Save your changes.

#### CLI

### Use the CLI to migrate a LIF

#### Step

Depending on whether you want to migrate a specific LIF or all the LIFs, perform the appropriate action:

| If you want to migrate...                          | Enter the following command...                                                   |
|----------------------------------------------------|----------------------------------------------------------------------------------|
| A specific LIF                                     | <code>network interface migrate</code>                                           |
| All the data and cluster-management LIFs on a node | <code>network interface migrate-all</code>                                       |
| All of the LIFs off of a port                      | <code>network interface migrate-all -node &lt;node&gt; -port &lt;port&gt;</code> |

The following example shows how to migrate a LIF named `datalif1` on the SVM `vs0` to the port `e0d` on node`0b`:

```
network interface migrate -vserver vs0 -lif datalif1 -dest-node node0b
-dest-port e0d
```

The following example shows how to migrate all the data and cluster-management LIFs from the current (local) node:

```
network interface migrate-all -node local
```

### Revert a LIF to its home port

You can revert a LIF to its home port after it fails over or is migrated to a different port either manually or automatically. If the home port of a particular LIF is unavailable, the LIF remains at its current port and is not reverted.

#### About this task

- If you administratively bring the home port of a LIF to the up state before setting the automatic revert option, the LIF is not returned to the home port.

- The LIF does not automatically revert unless the value of the "auto-revert" option is set to true.
- You must ensure that the "auto-revert" option is enabled for the LIFs to revert to their home ports.

The procedure you follow depends on the interface that you use—System Manager or the CLI:

### **System Manager**

#### **Use System Manager to revert a network interface to its home port**

##### **Steps**

1. Select **Network > Overview > Network Interfaces**.
2. Select  > **Revert** beside the network interface you want to change.
3. Select **Revert** to revert a network interface to its home port.

### **CLI**

#### **Use the CLI to revert a LIF to its home port**

##### **Step**

Revert a LIF to its home port manually or automatically:

| If you want to revert a LIF to its home port... | Then enter the following command...                                                         |
|-------------------------------------------------|---------------------------------------------------------------------------------------------|
| Manually                                        | <code>network interface revert -vserver vserver_name -lif lif_name</code>                   |
| Automatically                                   | <code>network interface modify -vserver vserver_name -lif lif_name -auto-revert true</code> |

### **ONTAP 9.8 and later: Recover from an incorrectly configured cluster LIF**

A cluster cannot be created when the cluster network is cabled to a switch but not all of the ports configured in the Cluster IPspace can reach the other ports configured in the Cluster IPspace.

#### **About this task**

In a switched cluster, if a cluster network interface (LIF) is configured on the wrong port, or if a cluster port is wired into the wrong network, the `cluster create` command can fail with the following error:

Not all local cluster ports have reachability to one another.  
Use the "network port reachability show -detail" command for more details.

The results of the `network port show` command might show that several ports are added to the Cluster IPspace because they are connected to a port that is configured with a cluster LIF. However, the results of the `network port reachability show -detail` command reveal which ports do not have connectivity to one another.

To recover from a cluster LIF configured on a port that is not reachable to the other ports configured with cluster LIFs, perform the following steps:

## Steps

1. Reset the home port of the cluster LIF to the correct port:

```
network port modify -home-port
```

2. Remove the ports that do not have cluster LIFs configured on them from the cluster broadcast domain:

```
network port broadcast-domain remove-ports
```

3. Create the cluster:

```
cluster create
```

## Result

When you complete the cluster creation, the system detects the correct configuration and places the ports into the correct broadcast domains.

## Delete a LIF

You can delete a network interface (LIF) that is no longer required.

### Before you begin

LIFs to be deleted must not be in use.

## Steps

1. Mark the LIFs you want to delete as administratively down using the following command:

```
network interface modify -vserver vserver_name -lif lif_name -status
-admin down
```

2. Use the `network interface delete` command to delete one or all LIFs:

| If you want to delete... | Enter the command ...                                                     |
|--------------------------|---------------------------------------------------------------------------|
| A specific LIF           | <code>network interface delete -vserver vserver_name -lif lif_name</code> |
| All LIFs                 | <code>network interface delete -vserver vserver_name -lif *</code>        |

The following command deletes the LIF mgmtlif2:

```
network interface delete -vserver vs1 -lif mgmtlif2
```

3. Use the `network interface show` command to confirm that the LIF is deleted.

## Configure virtual IP (VIP) LIFs

Some next-generation data centers use Network-Layer-3 mechanisms that require LIFs to be failed over across subnets. Beginning with ONTAP 9.5, VIP data LIFs and the associated routing protocol, border gateway protocol (BGP), are supported, which enable ONTAP to participate in these next-generation networks.

### About this task

A VIP data LIF is a LIF that is not part of any subnet and is reachable from all ports that host a BGP LIF in the same IPspace. A VIP data LIF eliminates the dependency of a host on individual network interfaces. Because multiple physical adapters carry the data traffic, the entire load is not concentrated on a single adapter and the associated subnet. The existence of a VIP data LIF is advertised to peer routers through the routing protocol, Border Gateway Protocol (BGP).

VIP data LIFs provide the following advantages:

- LIF portability beyond a broadcast domain or subnet: VIP data LIFs can fail over to any subnet in the network by announcing the current location of each VIP data LIF to routers through BGP.
- Aggregate throughput: VIP data LIFs can support aggregate throughput that exceeds the bandwidth of any individual port because the VIP LIFs can send or receive data from multiple subnets or ports simultaneously.

### Set up border gateway protocol (BGP)

Before creating VIP LIFs, you must set up BGP, which is the routing protocol used for announcing the existence of a VIP LIF to peer routers.

Beginning with ONTAP 9.9.1, VIP BGP provides default route automation using BGP peer grouping to simplify configuration.

ONTAP has a simple way to learn default routes using the BGP peers as next-hop routers when the BGP peer is on the same subnet. To use the feature, set the `-use-peer-as-next-hop` attribute to `true`. By default, this attribute is `false`.

If you have static routes configured, those are still preferred over these automated default routes.

### Before you begin

The peer router must be configured to accept a BGP connection from the BGP LIF for the configured autonomous system number (ASN).

ONTAP does not process any incoming route announcements from the router; therefore, you should configure the peer router to not send any route updates to the cluster.

### About this task

Setting up BGP involves optionally creating a BGP configuration, creating a BGP LIF, and creating a BGP peer group. ONTAP automatically creates a default BGP configuration with default values when the first BGP peer group is created on a given node. A BGP LIF is used to establish BGP TCP sessions with peer routers. For a peer router, a BGP LIF is the next hop to reach a VIP LIF. Failover is disabled for the BGP LIF. A BGP peer group advertises the VIP routes for all the SVMs in the peer group's IPspace.

Beginning with ONTAP 9.8, these fields have been added to the `network bgp peer-group` command:

- `-asn-prepend-type`
- `-asn-prepend-count`
- `-community`

These BGP attributes allows you to configure the AS Path and community attributes for the BGP peer group.

Beginning with ONTAP 9.9.1, these fields have been added:

- `-asn` or `-peer-asn` (4-byte value)  
The attribute itself is not new, but it now uses a 4-byte integer.
- `-med`
- `-use-peer-as-next-hop`

You can make advanced route selections with Multi-Exit Discriminator (MED) support for path prioritization. MED is an optional attribute in the BGP update message that tells routers to select the best route for the traffic. The MED is an unsigned 32-bit integer (0 - 4294967295); lower values are preferred.

 While ONTAP supports the above BGP attributes, routers need not honor them. NetApp highly recommends you confirm which attributes are supported by your router and configure BGP peer-groups accordingly. For details, refer to the BGP documentation provided by your router.

## Steps

1. Log in to the advanced privilege level:

```
set -privilege advanced
```

2. Optional: Create a BGP configuration or modify the default BGP configuration of the cluster by performing one of the following actions:

- a. Create a BGP configuration:

```
network bgp config create -node {node_name | local} -asn asn_integer
-holdtime
hold_time -routerid local_router_IP_address
```

Sample with a 2-byte ASN:

```
network bgp config create -node node1 -asn 65502 -holdtime 180
-routerid 1.1.1.1
```

Sample with a 4-byte ASN:

```
network bgp config create -node node1 -asn 85502 -holdtime 180
-routerid 1.1.1.1
```

b. Modify the default BGP configuration:

```
network bgp defaults modify -asn asn_integer -holdtime hold_time
network bgp defaults modify -asn 65502
```

- `asn_integer` specifies the ASN. Beginning with ONTAP 9.8, ASN for BGP supports a 2-byte non-negative integer. This is a 16-bit number (1 - 65534 available values). Beginning with ONTAP 9.9.1, ASN for BGP supports a 4-byte non-negative integer (1 - 4294967295). The default ASN is 65501. ASN 23456 is reserved for ONTAP session establishment with peers that do not announce 4-byte ASN capability.
- `hold_time` specifies the hold time in seconds. The default value is 180s.

3. Create a BGP LIF for the system SVM:

```
network interface create -vserver system_svm -lif lif_name -service
-policy default-route-announce -home-node home_node -home-port home_port
-address ip_address -netmask netmask
```

You can use the `default-route-announce` service policy for the BGP LIF or any custom service policy which contains the "management-bgp" service.

```
network interface create -vserver cluster1 -lif bgp1 -service-policy
default-route-announce -home-node cluster1-01 -home-port e0c -address
10.10.10.100 -netmask 255.255.255.0
```

4. Create a BGP peer group that is used to establish BGP sessions with the remote peer routers and configure the VIP route information that is advertised to the peer routers:

Sample 1: Create a peer group without an auto default route

In this case, the admin has to create a static route to the BGP peer.

```
network bgp peer-group create -peer-group group_name -ipspace
ipspace_name -bgp-lif bgp_lif -peer-address peer-router_ip_address -peer
-asn 65502 -route-preference integer
-asn-prepend-type <ASN_prepend_type> -asn-prepend-count integer -med
integer -community BGP community list <0-65535>:<0-65535>
```

```
network bgp peer-group create -peer-group group1 -ipspace Default -bgp
-lif bgp1 -peer-address 10.10.10.1 -peer-asn 65502 -route-preference 100
-asn-prepend-type local-asn -asn-prepend-count 2 -med 100 -community
9000:900,8000:800
```

## Sample 2: Create a peer group with an auto default route

```
network bgp peer-group create -peer-group group_name -ipspace
ipspace_name -bgp-lif bgp_lif -peer-address peer-router_ip_address -peer
-asn 65502 -use-peer-as-next-hop true -route-preference integer -asn
-prepend-type <ASN_prepend_type> -asn-prepend-count integer -med integer
-community BGP community list <0-65535>:<0-65535>
```

```
network bgp peer-group create -peer-group group1 -ipspace Default -bgp
-lif bgp1 -peer-address 10.10.10.1 -peer-asn 65502 -use-peer-as-next-hop
true -route-preference 100 -asn-prepend-type local ASN -asn-prepend
-count 2 -med 100 -community 9000:900,8000:800
```

### Create a virtual IP (VIP) data LIF

The existence of a VIP data LIF is advertised to peer routers through the routing protocol, Border Gateway Protocol (BGP).

#### Before you begin

- The BGP peer group must be set up and the BGP session for the SVM on which the LIF is to be created must be active.
- A static route to the BGP router or any other router in the BGP LIF's subnet must be created for any outgoing VIP traffic for the SVM.
- You should turn on multipath routing so that the outgoing VIP traffic can utilize all the available routes.

If multipath routing is not enabled, all the outgoing VIP traffic goes from a single interface.

#### Steps

1. Create a VIP data LIF:

```
network interface create -vserver svm_name -lif lif_name -role data
-data-protocol
{nfs|cifs|iscsi|fcache|none|fc-nvme} -home-node home_node -address
ip_address -is-vip true
```

A VIP port is automatically selected if you do not specify the home port with the `network interface create` command.

By default, the VIP data LIF belongs to the system-created broadcast domain named 'Vip', for each IPspace. You cannot modify the VIP broadcast domain.

A VIP data LIF is reachable simultaneously on all ports hosting a BGP LIF of an IPspace. If there is no active BGP session for the VIP's SVM on the local node, the VIP data LIF fails over to the next VIP port on the node that has a BGP session established for that SVM.

2. Verify that the BGP session is in the up status for the SVM of the VIP data LIF:

```
network bgp vserver-status show

Node Vserver bgp status

node1 vs1 up
```

If the BGP status is `down` for the SVM on a node, the VIP data LIF fails over to a different node where the BGP status is `up` for the SVM. If BGP status is `down` on all the nodes, the VIP data LIF cannot be hosted anywhere, and has LIF status as `down`.

#### **Commands for managing the BGP**

Beginning with ONTAP 9.5, you use the `network bgp` commands to manage the BGP sessions in ONTAP.

#### **Manage BGP configuration**

| If you want to...                                  | Use this command...                          |
|----------------------------------------------------|----------------------------------------------|
| Create a BGP configuration                         | <code>network bgp config create</code>       |
| Modify BGP configuration                           | <code>network bgp config modify</code>       |
| Delete BGP configuration                           | <code>network bgp config delete</code>       |
| Display BGP configuration                          | <code>network bgp config show</code>         |
| Displays the BGP status for the SVM of the VIP LIF | <code>network bgp vserver-status show</code> |

#### **Manage BGP default values**

| If you want to...          | Use this command...                      |
|----------------------------|------------------------------------------|
| Modify BGP default values  | <code>network bgp defaults modify</code> |
| Display BGP default values | <code>network bgp defaults show</code>   |

#### **Manage BGP peer groups**

| If you want to...                   | Use this command...                        |
|-------------------------------------|--------------------------------------------|
| Create a BGP peer group             | <code>network bgp peer-group create</code> |
| Modify a BGP peer group             | <code>network bgp peer-group modify</code> |
| Delete a BGP peer group             | <code>network bgp peer-group delete</code> |
| Display BGP peer groups information | <code>network bgp peer-group show</code>   |
| Rename a BGP peer group             | <code>network bgp peer-group rename</code> |

[ONTAP 9 commands](#)

## Configure host-name resolution

### Overview

ONTAP must be able to translate host names to numerical IP addresses in order to provide access to clients and to access services. You must configure storage virtual machines (SVMs) to use local or external name services to resolve host information. ONTAP supports configuring an external DNS server or configuring the local hosts file for host name resolution.

When using an external DNS server, you can configure Dynamic DNS (DDNS), which automatically sends new or changed DNS information from your storage system to the DNS server. Without dynamic DNS updates, you must manually add DNS information (DNS name and IP address) to the identified DNS servers when a new system is brought online or when existing DNS information changes. This process is slow and error-prone. During disaster recovery, manual configuration can result in a long downtime.

### Configure DNS for host-name resolution

You use DNS to access either local or remote sources for host information. You must configure DNS to access one or both of these sources.

ONTAP must be able to look up host information to provide proper access to clients. You must configure name services to enable ONTAP to access local or external DNS services to obtain the host information.

ONTAP stores name service configuration information in a table that is the equivalent of the /etc/nsswitch.conf file on UNIX systems.

### Configure an SVM and data LIFs for host-name resolution using an external DNS server

You can use the vserver services name-service dns command to enable DNS on an SVM, and configure it to use DNS for host-name resolution. Host names are resolved using external DNS servers.

#### Before you begin

A site-wide DNS server must be available for host name lookups.

You should configure more than one DNS server to avoid a single-point-of-failure. The vserver services name-service dns create command issues a warning if you enter only one DNS server name.

#### About this task

See [Configure dynamic DNS services](#) for more information about configuring dynamic DNS on the SVM.

#### Steps

1. Enable DNS on the SVM:

```
vserver services name-service dns create -vserver vserver_name -domains domain_name - name-servers ip_addresses -state enabled
```

The following command enables external DNS server servers on the SVM vs1:

```
vserver services name-service dns create -vserver <vs1.example.com>
-domains <example.com> -name-servers <192.0.2.201,192.0.2.202> -state
<enabled>
```

The vserver services name-service dns create command performs an automatic configuration validation and reports an error message if ONTAP cannot contact the name server.

## 2. Enable DNS on LIFs owned by the SVM:

| If you are                          | Use this command:                               |
|-------------------------------------|-------------------------------------------------|
| Modifying an existing LIF zone-name | network interface modify -lif lifname -dns-zone |
| Creating a new LIF zone-name        | network interface create -lif lifname -dns-zone |

```
vserver services name-service dns create -vserver <vs1> -domains
<example.com> -name-servers <192.0.2.201, 192.0.2.202> -state <enabled>
network interface modify -lif <datalif1> -dns-zone
<zonenumber.whatever.com>
```

## 3. Validate the status of the name servers by using the vserver services name-service dns check command.

```
vserver services name-service dns check -vserver vs1.example.com
VserverName Server Status Status Details
----- -----
vs1.example.com 10.0.0.50 up Response time (msec): 2
vs1.example.com 10.0.0.51 up Response time (msec): 2
```

## Configure the Name Service Switch Table for Host-Name Resolution

You must configure the name service switch table correctly to enable ONTAP to consult local or external name service to retrieve host information.

### Before you begin

You must have decided which name service to use for host mapping in your environment.

### Steps

#### 1. Add the necessary entries to the name service switch table:

```
vserver services name-service <ns-switch> create -vserver <vserver_name>
-database <database_name> -source <source_names>
```

2. Verify that the name service switch table contains the expected entries in the desired order:

```
vserver services name-service <ns-switch> show -vserver <vserver_name>
```

### Example

The following example creates an entry in the name service switch table for SVM vs1 to first use the local hosts file and then an external DNS server to resolve host names:

```
vserver services name-service ns-switch create -vserver vs1 -database
hosts -sources files dns
```

### Manage the hosts table (cluster administrators only)

A cluster administrator can add, modify, delete, and view the host name entries in the hosts table of the admin storage virtual machine (SVM). An SVM administrator can configure the host name entries only for the assigned SVM.

#### Commands for managing local host-name entries

You can use the vserver services name-service dns hosts command to create, modify, or delete DNS host table entries.

When you are creating or modifying the DNS host-name entries, you can specify multiple alias addresses separated by commas.

| If you want to...            | Use this command...                            |
|------------------------------|------------------------------------------------|
| Create a DNS host-name entry | vserver services name-service dns hosts create |
| Modify a DNS host-name entry | vserver services name-service dns hosts modify |
| Delete a DNS host-name entry | vserver services name-service dns hosts delete |

For more information, see the [ONTAP 9 commands](#) for the vserver services name-service dns hosts commands.

### Balance network loads to optimize user traffic (cluster administrators only)

#### Overview

You can configure your cluster to serve client requests from appropriately loaded LIFs.

This results in a more balanced utilization of LIFs and ports, which in turn allows for better performance of the cluster.

DNS load balancing helps in selecting an appropriately loaded data LIF and balancing user network traffic across all available ports (physical, interface groups, and VLANs).

With DNS load balancing, LIFs are associated with the load balancing zone of an SVM. A site-wide DNS server is configured to forward all DNS requests and return the least-loaded LIF based on the network traffic and the availability of the port resources (CPU usage, throughput, open connections, and so on). DNS load balancing provides the following benefits:

- New client connections balanced across available resources.
- No manual intervention required for deciding which LIFs to use when mounting a particular SVM.
- DNS load balancing supports NFSv3, NFSv4, NFSv4.1, SMB 2.0, SMB 2.1, and SMB 3.0.

## How DNS load balancing works

Clients mount an SVM by specifying an IP address (associated with a LIF) or a host name (associated with multiple IP addresses). By default, LIFs are selected by the site-wide DNS server in a round-robin manner, which balances the workload across all LIFs.

Round-robin load balancing can result in overloading some LIFs, so you have the option of using a DNS load balancing zone that handles the host-name resolution in an SVM. Using a DNS load balancing zone, ensures better balance of the new client connections across available resources, leading to improved performance of the cluster.

A DNS load balancing zone is a DNS server inside the cluster that dynamically evaluates the load on all LIFs and returns an appropriately loaded LIF. In a load balancing zone, DNS assigns a weight (metric), based on the load, to each LIF.

Every LIF is assigned a weight based on its port load and CPU utilization of its home node. LIFs that are on less-loaded ports have a higher probability of being returned in a DNS query. Weights can also be manually assigned.

## Create a DNS load balancing zone

You can create a DNS load balancing zone to facilitate the dynamic selection of a LIF based on the load, that is, the number of clients mounted on a LIF. You can create a load balancing zone while creating a data LIF.

### Before you begin

The DNS forwarder on the site-wide DNS server must be configured to forward all requests for the load balancing zone to the configured LIFs.

The Knowledgebase article [How to set up DNS load balancing in Cluster-Mode](#) on the NetApp Support Site contains more information about configuring DNS load balancing using conditional forwarding.

### About this task

- Any data LIF can respond to DNS queries for a DNS load balancing zone name.
- A DNS load balancing zone must have a unique name in the cluster, and the zone name must meet the following requirements:

- It should not exceed 256 characters.
- It should include at least one period.
- The first and the last character should not be a period or any other special character.
- It cannot include any spaces between characters.
- Each label in the DNS name should not exceed 63 characters.

A label is the text appearing before or after the period. For example, the DNS zone named storage.company.com has three labels.

## Step

Use the `network interface create` command with the `dns-zone` option to create a DNS load balancing zone.

If the load balancing zone already exists, the LIF is added to it. For more information about the command, see [ONTAP 9 commands](#).

The following example demonstrates how to create a DNS load balancing zone named storage.company.com while creating the LIF `lif1`:

```
network interface create -vserver vs0 -lif lif1 -home-node node1
-hom-port e0c -address 192.0.2.129 -netmask 255.255.255.128 -dns-zone
storage.company.com
```

## Add or remove a LIF from a load balancing zone

You can add or remove a LIF from the DNS load balancing zone of a virtual machine (SVM). You can also remove all the LIFs simultaneously from a load balancing zone.

### Before you begin

- All the LIFs in a load balancing zone should belong to the same SVM.
- A LIF can be a part of only one DNS load balancing zone.
- Failover groups for each subnet must have been set up, if the LIFs belong to different subnets.

### About this task

A LIF that is in the administrative down status is temporarily removed from the DNS load balancing zone. When the LIF returns to the administrative up status, the LIF is automatically added to the DNS load balancing zone.

## Step

Add a LIF to or remove a LIF from a load balancing zone:

|                   |          |
|-------------------|----------|
| If you want to... | Enter... |
|-------------------|----------|

|                     |                                                                                                                                                                                                                                                                                    |
|---------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Add a LIF           | <pre>network interface modify -vserver vserver_name -lif lif_name -dns-zone zone_name</pre> <b>Example:</b> <pre>network interface modify -vserver vs1 -lif data1 -dns -zone cifs.company.com</pre>                                                                                |
| Remove a single LIF | <pre>network interface modify -vserver vserver_name -lif lif_name -dns-zone none</pre> <b>Example:</b> <pre>network interface modify -vserver vs1 -lif data1 -dns -zone none</pre>                                                                                                 |
| Remove all LIFs     | <pre>network interface modify -vserver vserver_name -lif * -dns-zone none</pre> <b>Example:</b> <pre>network interface modify -vserver vs0 -lif * -dns-zone none</pre> <p>You can remove an SVM from a load balancing zone by removing all the LIFs in the SVM from that zone.</p> |

## Secure your network

### Configure network security using federal information processing standards (FIPS)

ONTAP is compliant in the Federal Information Processing Standards (FIPS) 140-2 for all SSL connections. You can turn on and off SSL FIPS mode, set SSL protocols globally, and turn off any weak ciphers such as RC4 within ONTAP.

By default, SSL on ONTAP is set with FIPS compliance disabled and SSL protocol enabled with the following:

- TLSv1.3 (beginning in ONTAP 9.11.1)
- TLSv1.2
- TLSv1.1
- TLSv1

When SSL FIPS mode is enabled, SSL communication from ONTAP to external client or server components outside of ONTAP will use FIPS compliant crypto for SSL.

If you want administrator accounts to access SVMs with an SSH public key, you must ensure that the host key algorithm is supported before enabling SSL FIPS mode.

**Note:** Host key algorithm support has changed in ONTAP 9.11.1 and later releases.

| ONTAP release | Supported key types | Unsupported key types |
|---------------|---------------------|-----------------------|
|---------------|---------------------|-----------------------|

|                    |                                    |                                                                   |
|--------------------|------------------------------------|-------------------------------------------------------------------|
| 9.11.1 and later   | ecdsa-sha2-nistp256                | rsa-sha2-512<br>rsa-sha2-256<br>ssh-ed25519<br>ssh-dss<br>ssh-rsa |
| 9.10.1 and earlier | ecdsa-sha2-nistp256<br>ssh-ed25519 | ssh-dss<br>ssh-rsa                                                |

Existing SSH public key accounts without the supported key algorithms must be reconfigured with a supported key type before enabling FIPS, or the administrator authentication will fail.

For more information, see [Enable SSH public key accounts](#).

For more information about SSL FIPS mode configuration, see the `security config modify` man page.

### Enable FIPS

It is recommended that all secure users adjust their security configuration immediately after system installation or upgrade. When SSL FIPS mode is enabled, SSL communication from ONTAP to external client or server components outside of ONTAP will use FIPS compliant crypto for SSL.

When FIPS is enabled, you cannot install or create a certificate with an RSA key length of 4096.

### Steps

1. Change to advanced privilege level:

```
set -privilege advanced
```

2. Enable FIPS:

```
security config modify -interface SSL -is-fips-enabled true
```

3. When prompted to continue, enter `y`

4. If you are running ONTAP 9.8 or earlier manually reboot each node in the cluster one by one. Beginning in ONTAP 9.9.1, rebooting is not required.

### Example

If you are running ONTAP 9.9.1 or later, you will not see the warning message.

```
security config modify -interface SSL -is-fips-enabled true

Warning: This command will enable FIPS compliance and can potentially
cause some non-compliant components to fail. MetroCluster and Vserver DR
require FIPS to be enabled on both sites in order to be compatible.
Do you want to continue? {y|n}: y

Warning: When this command completes, reboot all nodes in the cluster.
This is necessary to prevent components from failing due to an
inconsistent security configuration state in the cluster. To avoid a
service outage, reboot one node at a time and wait for it to completely
initialize before rebooting the next node. Run "security config status
show" command to monitor the reboot status.
Do you want to continue? {y|n}: y
```

## Disable FIPS

If you are still running an older system configuration and want to configure ONTAP with backward compatibility, you can turn on SSLv3 only when FIPS is disabled.

### Steps

1. Change to advanced privilege level:

```
set -privilege advanced
```

2. Disable FIPS by typing:

```
security config modify -interface SSL -is-fips-enabled false
```

3. When prompted to continue, enter y.

4. If you are running ONTAP 9.8 or earlier, manually reboot each node in the cluster. Beginning in ONTAP 9.9.1, rebooting is not required.

### Example

If you are running ONTAP 9.9.1 or later, you will not see the warning message.

```
security config modify -interface SSL -supported-protocols SSLv3

Warning: Enabling the SSLv3 protocol may reduce the security of the
interface, and is not recommended.
Do you want to continue? {y|n}: y

Warning: When this command completes, reboot all nodes in the cluster.
This is necessary to prevent components from failing due to an
inconsistent security configuration state in the cluster. To avoid a
service outage, reboot one node at a time and wait for it to completely
initialize before rebooting the next node. Run "security config status
show" command to monitor the reboot status.
Do you want to continue? {y|n}: y
```

### **View FIPS compliance status**

You can see whether the entire cluster is running the current security configuration settings.

#### **Steps**

1. One by one, reboot each node in the cluster.

Do not reboot all cluster nodes simultaneously. A reboot is required to make sure that all applications in the cluster are running the new security configuration, and for all changes to FIPS on/off mode, protocols, and ciphers.

2. View the current compliance status:

```
security config show
```

#### **Example**

```
security config show

 Cluster Cluster
Security
Interface FIPS Mode Supported Protocols Supported Ciphers Config
Ready
----- ----- -----
----- ----- -----
SSL false TLSv1_2, TLSv1_1, TLSv1 ALL:!LOW:!aNULL: yes
 !EXP:!eNULL
```

### **Configure IP security (IPsec) over wire encryption**

Beginning with ONTAP 9.8, ONTAP uses the IPsec protocol in transport mode to ensure data is continuously secure and encrypted, even while in transit. IPsec offers data encryption for all IP traffic including the NFS, iSCSI, and SMB protocols. IPsec provides

the only encryption in flight option for iSCSI traffic.

Beginning with ONTAP 9.9.1, the encryption algorithms used by IPsec are FIPS 140-2 validated. The algorithms are generated by the NetApp Cryptographic Module in ONTAP which carries the FIPS 140-2 validation.

Beginning with ONTAP 9.10.1, you can use either pre-shared keys (PSKs) or certificates for authentication with IPsec. Previously, only PSKs were supported with IPsec.

Beginning with ONTAP 9.12.1, front-end host protocol IPsec support is available in MetroCluster IP and MetroCluster fabric-attached configurations.

- IPsec support in MetroCluster clusters is limited to front-end host traffic and is not supported on MetroCluster intercluster LIFs.

After IPsec is configured, network traffic between the client and ONTAP is protected with preventive measures to combat replay and man-in-the-middle (MITM) attacks.

For NetApp SnapMirror and cluster peering traffic encryption, cluster peering encryption (CPE), transport layer security (TLS) is still recommended over IPsec for secure in-transit over the wire. This is because TLS has better performance than IPsec.

While IPsec capability is enabled on the cluster, the network requires a Security Policy Database (SPD) entry to match the to-be-protected traffic and to specify protection details (such as cipher suite and authentication method) before traffic can flow. A corresponding SPD entry is also needed on each client. The SPD requirement is needed for both PSK and certification authentication methods.

#### **Enable IPsec on the cluster**

You can enable IPsec on the cluster to ensure data is continuously secure and encrypted, even while in transit.

#### **Steps**

1. Discover if IPsec is enabled already:

```
security ipsec config show
```

If the result includes IPsec Enabled: false, proceed to the next step.

2. Enable IPsec:

```
security ipsec config modify -is-enabled true
```

3. Run the discovery command again:

```
security ipsec config show
```

The result now includes IPsec Enabled: true.

#### **Preparing for IPsec policy creation with certificate authentication**

You can skip this step if you are only using pre-shared keys PSKs for authentication and will not use certificate authentication.

Before creating an IPsec policy that uses certificates for authentication you must ensure that the following pre-

requisites are met:

- Both ONTAP and the client must have the other party's CA certificate installed so that the end entity (either ONTAP or the client) certificates are verifiable by both sides
- A certificate is installed for the ONTAP LIF that participates in the policy

ONTAP LIFs can share certificates. A one-to-one mapping between certificates and LIFs is not required.

## Steps

1. You must install all CA certificates used during the mutual authentication, including both ONTAP-side and client-side CAs, to ONTAP certificate management unless it is already installed (as is the case of an ONTAP self-signed root-CA).

### Sample command

```
cluster::> security certificate install -vserver svm_name -type server-ca
-cert-name my_ca_cert
```

2. To ensure that the CA installed is within the IPsec CA searching path during authentication, add the ONTAP certificate management CAs to the IPsec module using the "security ipsec ca-certificate add" command.

### Sample command

```
cluster::> security ipsec ca-certificate add -vserver svm_name -ca-certs
my_ca_cert
```

3. Create and install a certificate for use by the ONTAP LIF. The issuer CA of this certificate must already be installed to ONTAP and added to IPsec.

### Sample command

```
cluster::> security certificate install -vserver svm_name -type server -cert
-name my_nfs_server_cert
```

For more information about certificates in ONTAP, see the security certificate commands in the ONTAP 9 documentation.

## Define the security policy database (SPD)

IPsec requires an SPD entry before allowing traffic to flow on the network. This is true whether you are using a PSK or a certificate for authentication.

## Step

1. Use the `security ipsec policy create` command to:

- a. Select the ONTAP IP address or subnet of IP addresses to participate in the IPsec transport.
- b. Select the client IP addresses that will connect to the ONTAP IP addresses.

The client must support Internet Key Exchange version 2 (IKEv2) with a pre-shared key (PSK).

- c. Optional. Select the upper layer protocols (UDP, TCP, ICMP, etc.), the local port numbers, and the remote port numbers to protect. The corresponding parameters are `protocols`, `local-ports` and `remote-ports` respectively.

Skip this step to protect all traffic between the ONTAP IP address and client IP address. Protecting all traffic is the default.

- d. Either enter PSK or PKI for the auth-method parameter for the desired authentication method.
  - i. If you enter a PSK, after finishing all other optional parameters, hit <enter> for the prompt to enter and verify the pre-shared key.
  - ii. If you enter a PKI, you need to also enter the cert-name, local-identity, remote-identity parameters. If the remote side certificate's identity is unknown or if multiple client identities are expected, enter the special word ANYTHING.

#### **Sample command for PSK authentications**

```
security ipsec policy create -vserver <vs1> -name <test34> -local-ip
-subnets <192.168.134.34/32> -remote-ip-subnets <192.168.134.44/32>
Enter the preshared key for IPsec Policy _test34_ on Vserver _vs1_:
```

#### **Sample command for certificate authentications**

```
security ipsec policy create -vserver vs1 -name test34 -local-ip-subnets
192.168.134.34/32 -remote-ip-subnets 192.168.134.44/32 -local-ports 2049
-protocols tcp -auth-method PKI -cert-name my_nfs_server_cert -local
-identity CN=netapp.ipsec.lif1.vs0 -remote-identity ANYTHING
```

IP traffic cannot flow between the client and server until both ONTAP and the client have setup the matching IPsec policies, and authentication credentials (either PSK or certificate) are in place on both sides. For details, see the client side's IPsec configuration.

#### **Use IPsec identities**

For the pre-shared key authentication method, identities are optional unless required by an IPsec client (such as Libreswan). For the PKI/certificate authentication method, both local and remote identities are mandatory. The identities specify what identity is certified within each side's certificate and are used in the verification process. If the remote-identity is unknown or if it could be many different identities, use the special identity ANYTHING.

#### **About this task**

Within ONTAP, identities are specified by modifying the SPD entry or during SPD policy creation. The SPD can be an IP address or string format identity name.

#### **Step**

To modify an existing SPD's identity settings, use the following command:

```
security ipsec policy modify
```

#### **Sample command**

```
security ipsec policy modify -vserver vs1 -name test34 -local-identity
192.168.134.34 -remote-identity client.fooboo.com
```

#### **IPsec multiple client configuration**

When a small number of clients need to leverage IPsec, using a single SPD entry for each client is sufficient. However, when hundreds or even thousands of clients need to leverage IPsec, NetApp recommends using an

## About this task

ONTAP supports connecting multiple clients across many networks to a single SVM IP address with IPsec enabled. You can accomplish this using one of the following methods:

- **Subnet configuration**

To allow all clients on a particular subnet (192.168.134.0/24 for example) to connect to a single SVM IP address using a single SPD policy entry, you must specify the `remote-ip-subnets` in subnet form. Additionally, you must specify the `remote-identity` field with the correct client side identity.

 When using a single policy entry in a subnet configuration, IPsec clients in that subnet share the IPsec identity and pre-shared key (PSK). However, this is not true with certificate authentication.

When using certificates each client can use either their own unique certificate or a shared certificate to authenticate. ONTAP IPsec checks the validity of the certificate based on the CAs installed on its local trust store. ONTAP also supports certificate revocation list (CRL) checking.

- **Allow all clients configuration**

To allow any client, regardless of their source IP address, to connect to the SVM IPsec-enabled IP address, use the `0.0.0.0/0` wild card when specifying the `remote-ip-subnets` field.

Additionally, you must specify the `remote-identity` field with the correct client side identity. For certificate authentication, you can enter ANYTHING.

Also, when the `0.0.0.0/0` wild card is used, you must configure a specific local or remote port number to use. For example, NFS port 2049.

### Step

1. Use one of the following commands to configure IPsec for multiple clients:

- a. If you are using a **subnet configuration** to support multiple IPsec clients:

```
security ipsec policy create -vserver vserver_name -name policy_name
-local-ip-subnets IPsec_IP_address/32 -remote-ip-subnets
IP_address/subnet -local-identity local_id -remote-identity remote_id
```

#### Sample command

```
security ipsec policy create -vserver vs1 -name subnet134 -local-ip
-subnets 192.168.134.34/32 -remote-ip-subnets 192.168.134.0/24 -local
-identity ontap_side_identity -remote-identity client_side_identity
```

- b. If you are using an **allow all clients configuration** to support multiple IPsec clients:

```
security ipsec policy create -vserver vserver_name -name policy_name
-local-ip-subnets IPsec_IP_address/32 -remote-ip-subnets 0.0.0.0/0 -local
-ports port_number -local-identity local_id -remote-identity remote_id
```

#### Sample command

```
security ipsec policy create -vserver vs1 -name test35 -local-ip-subnets
IPsec_IP_address/32 -remote-ip-subnets 0.0.0.0/0 -local-ports 2049 -local
```

```
-identity ontap_side_identity -remote-identity client_side_identity
```

## IPsec statistics

Through negotiation, a security channel called an IKE Security Association (SA) can be established between the ONTAP SVM IP address and the client IP address. IPsec SAs are installed on both endpoints to do the actual data encryption and decryption work.

You can use statistics commands to check the status of both IPsec SAs and IKE SAs.

### Sample commands

IKE SA sample command:

```
security ipsec show-ikesasa -node hosting_node_name_for_svm_ip
```

IPsec SA sample command and output:

```
security ipsec show-ipsecsa -node hosting_node_name_for_svm_ip
```

```
cluster1::> security ipsec show-ikesa -node cluster1-node1
 Policy Local Remote
Vserver Name Address Address Initiator-SPI State
----- -----

vs1 test34 192.168.134.34 192.168.134.44 c764f9ee020cec69
ESTABLISHED
```

IPsec SA sample command and output:

```
security ipsec show-ipsecsa -node hosting_node_name_for_svm_ip

cluster1::> security ipsec show-ipsecsa -node cluster1-node1
 Policy Local Remote Inbound Outbound
Vserver Name Address Address SPI SPI
State
----- -----

INSTALLED
```

## Configure firewall policies for LIFs

Setting up a firewall enhances the security of the cluster and helps prevent unauthorized access to the storage system. By default, the onboard firewall is configured to allow remote access to a specific set of IP services for data, management, and intercluster

## LIFs

Beginning with ONTAP 9.10.1:

- Firewall policies are deprecated and are replaced by LIF service policies. Previously, the onboard firewall was managed using firewall policies. This functionality is now accomplished using a LIF service policy.
- All firewall policies are empty and do not open any ports in the underlying firewall. Instead, all ports must be opened using a LIF service policy.
- No action is required after an upgrade to 9.10.1 or later to transition from firewall policies to LIF service policies. The system automatically constructs LIF service policies consistent with the firewall policies in use in the previous ONTAP release. If you use scripts or other tools that create and manage custom firewall policies, you might need to upgrade those scripts to create custom service policies instead.

To learn more, see [LIFs and service policies in ONTAP 9.6 and later](#).

Firewall policies can be used to control access to management service protocols such as SSH, HTTP, HTTPS, Telnet, NTP, NDMP, NDMPS, RSH, DNS, or SNMP. Firewall policies cannot be set for data protocols such as NFS or SMB.

You can manage firewall service and policies in the following ways:

- Enabling or disabling firewall service
- Displaying the current firewall service configuration
- Creating a new firewall policy with the specified policy name and network services
- Applying a firewall policy to a logical interface
- Creating a new firewall policy that is an exact copy of an existing policy

You can use this to make a policy with similar characteristics within the same SVM, or to copy the policy to a different SVM.

- Displaying information about firewall policies
- Modifying the IP addresses and netmasks that are used by a firewall policy
- Deleting a firewall policy that is not being used by a LIF

### Firewall policies and LIFs

LIF firewall policies are used to restrict access to the cluster over each LIF. You need to understand how the default firewall policy affects system access over each type of LIF, and how you can customize a firewall policy to increase or decrease security over a LIF.

When configuring a LIF using the `network interface create` or `network interface modify` command, the value specified for the `-firewall-policy` parameter determines the service protocols and IP addresses that are allowed access to the LIF.

In many cases you can accept the default firewall policy value. In other cases, you might need to restrict access to certain IP addresses and certain management service protocols. The available management service protocols include SSH, HTTP, HTTPS, Telnet, NTP, NDMP, NDMPS, RSH, DNS, and SNMP.

The firewall policy for all cluster LIFs defaults to "" and cannot be modified.

The following table describes the default firewall policies that are assigned to each LIF, depending on their role

(ONTAP 9.5 and earlier) or service policy (ONTAP 9.6 and later), when you create the LIF:

| Firewall policy | Default service protocols                              | Default access          | LIFs applied to                                              |
|-----------------|--------------------------------------------------------|-------------------------|--------------------------------------------------------------|
| mgmt            | dns, http, https, ndmp, ndmps, ntp, snmp, ssh          | Any address (0.0.0.0/0) | Cluster management, SVM management, and node management LIFs |
| mgmt-nfs        | dns, http, https, ndmp, ndmps, ntp, portmap, snmp, ssh | Any address (0.0.0.0/0) | Data LIFs that also support SVM management access            |
| intercluster    | https, ndmp, ndmps                                     | Any address (0.0.0.0/0) | All intercluster LIFs                                        |
| data            | dns, ndmp, ndmps, portmap                              | Any address (0.0.0.0/0) | All data LIFs                                                |

#### Portmap service configuration

The portmap service maps RPC services to the ports on which they listen.

The portmap service was always accessible in ONTAP 9.3 and earlier, became configurable in ONTAP 9.4 through ONTAP 9.6, and is managed automatically beginning with ONTAP 9.7.

- In ONTAP 9.3 and earlier, the portmap service (rpcbind) was always accessible on port 111 in network configurations that relied on the built-in ONTAP firewall rather than a third-party firewall.
- From ONTAP 9.4 through ONTAP 9.6, you can modify firewall policies to control whether the portmap service is accessible on particular LIFs.
- Beginning with ONTAP 9.7, the portmap firewall service is eliminated. Instead, the portmap port is opened automatically for all LIFs that support the NFS service.

#### Portmap service is configurable in the firewall in ONTAP 9.4 through ONTAP 9.6.

The remainder of this topic discusses how to configure the portmap firewall service for ONTAP 9.4 through ONTAP 9.6 releases.

Depending on your configuration, you may be able to disallow access to the service on specific types of LIFs, typically management and intercluster LIFs. In some circumstances, you might even be able to disallow access on data LIFs.

#### What behavior you can expect

The ONTAP 9.4 through ONTAP 9.6 behavior is designed to provide a seamless transition on upgrade. If the portmap service is already being accessed over specific types of LIFs, it will continue to be accessible over those types of LIFs. As in previous ONTAP versions, you can specify the services accessible within the firewall in the firewall policy for the LIF type.

All nodes in the cluster must be running ONTAP 9.4 through ONTAP 9.6 for the behavior to take effect. Only inbound traffic is affected.

The new rules are as follows:

- On upgrade to release 9.4 through 9.6, ONTAP adds the portmap service to all existing firewall policies, default or custom.
- When you create a new cluster or new IPspace, ONTAP adds the portmap service only to the default data policy, not to the default management or intercluster policies.
- You can add the portmap service to default or custom policies as needed, and remove the service as needed.

### **How to add or remove the portmap service**

To add the portmap service to an SVM or cluster firewall policy (make it accessible within the firewall), enter:

```
system services firewall policy create -vserver SVM -policy
mgmt|intercluster|data|custom -service portmap
```

To remove the portmap service from an SVM or cluster firewall policy (make it inaccessible within the firewall), enter:

```
system services firewall policy delete -vserver SVM -policy
mgmt|intercluster|data|custom -service portmap
```

You can use the network interface modify command to apply the firewall policy to an existing LIF. For complete command syntax, see [ONTAP 9 commands](#).

### **Create a firewall policy and assigning it to a LIF**

Default firewall policies are assigned to each LIF when you create the LIF. In many cases, the default firewall settings work well and you do not need to change them. If you want to change the network services or IP addresses that can access a LIF, you can create a custom firewall policy and assign it to the LIF.

### **About this task**

- You cannot create a firewall policy with the policy name data, intercluster, cluster, or mgmt.

These values are reserved for the system-defined firewall policies.

- You cannot set or modify a firewall policy for cluster LIFs.

The firewall policy for cluster LIFs is set to 0.0.0.0/0 for all services types.

- If you need to remove a service from a policy, you must delete the existing firewall policy and create a new policy.
- If IPv6 is enabled on the cluster, you can create firewall policies with IPv6 addresses.

After IPv6 is enabled, data, intercluster, and mgmt firewall policies include ::/0, the IPv6 wildcard, in their list of accepted addresses.

- When using System Manager to configure data protection functionality across clusters, you must ensure that the intercluster LIF IP addresses are included in the allowed list, and that HTTPS service is allowed on both the intercluster LIFs and on your company-owned firewalls.

By default, the intercluster firewall policy allows access from all IP addresses (0.0.0.0/0, or ::/0 for IPv6) and enables HTTPS, NDMP, and NDMPS services. If you modify this default policy, or if you create your own firewall policy for intercluster LIFs, you must add each intercluster LIF IP address to the allowed list and enable HTTPS service.

- Beginning with ONTAP 9.6, the HTTPS and SSH firewall services are not supported.

In ONTAP 9.6, the `management-https` and `management-ssh` LIF services are available for HTTPS and SSH management access.

## Steps

- Create a firewall policy that will be available to the LIFs on a specific SVM:

```
system services firewall policy create -vserver vserver_name -policy
policy_name -service network_service -allow-list ip_address/mask
```

You can use this command multiple times to add more than one network service and list of allowed IP addresses for each service in the firewall policy.

- Verify that the policy was added correctly by using the `system services firewall policy show` command.
- Apply the firewall policy to a LIF:

```
network interface modify -vserver vserver_name -lif lif_name -firewall-policy
policy_name
```

- Verify that the policy was added correctly to the LIF by using the `network interface show -fields firewall-policy` command.

### Example of creating a firewall policy and applying it to a LIF

The following command creates a firewall policy named `data_http` that enables HTTP and HTTPS protocol access from IP addresses on the 10.10 subnet, applies that policy to the LIF named `data1` on SVM `vs1`, and then shows all of the firewall policies on the cluster:

```
system services firewall policy create -vserver vs1 -policy data_http
-service http - allow-list 10.10.0.0/16
```

```

system services firewall policy show

## Commands for managing firewall service and policies

You can use the system services firewall commands to manage firewall service, the system services firewall policy commands to manage firewall policies, and the network interface modify command to manage firewall settings for LIFs.

| If you want to...                                                        | Use this command...                                    |
|--------------------------------------------------------------------------|--------------------------------------------------------|
| Enable or disable firewall service                                       | system services firewall modify                        |
| Display the current configuration for firewall service                   | system services firewall show                          |
| Create a firewall policy or add a service to an existing firewall policy | system services firewall policy create                 |
| Apply a firewall policy to a LIF                                         | network interface modify -lif lifname -firewall-policy |
| Modify the IP addresses and netmasks associated with a firewall policy   | system services firewall policy modify                 |
| Display information about firewall policies                              | system services firewall policy show                   |
| Create a new firewall policy that is an exact copy of an existing policy | system services firewall policy clone                  |
| Delete a firewall policy that is not used by a LIF                       | system services firewall policy delete                 |

For more information, see the man pages for the system services firewall, system services firewall policy, and network interface modify commands in [ONTAP 9 commands](#).

## Configure QoS marking (cluster administrators only)

### Overview

Network Quality of Service (QoS) marking helps you to prioritize different traffic types based on the network conditions to effectively utilize the network resources. You can set the differentiated services code point (DSCP) value of the outgoing IP packets for the supported traffic types per IPspace.

### DSCP marking for UC compliance

You can enable differentiated services code point (DSCP) marking on outgoing (egress) IP packet traffic for a given protocol with a default or user-provided DSCP code. DSCP marking is a mechanism for classifying and managing network traffic and is a component of Unified Capability (UC) compliance.

DSCP marking (also known as *QoS marking* or *quality of service marking*) is enabled by providing an IPspace, protocol, and DSCP value. The protocols on which DSCP marking can be applied are NFS, SMB, iSCSI, SnapMirror, NDMP, FTP, HTTP/HTTPS, SSH, Telnet, and SNMP.

If you do not provide a DSCP value when enabling DSCP marking for a given protocol, a default is used:

- The default value for data protocols/traffic is 0x0A (10).
- The default value for control protocols/traffic is 0x30 (48).

## Modify QoS marking values

You can modify the Quality of Service (QoS) marking values for different protocols, for each IPspace.

### Before you begin

All nodes in the cluster must be running the same version of ONTAP.

### Step

Modify QoS marking values by using the `network qos-marking modify` command.

- The `-ipspace` parameter specifies the IPspace for which the QoS marking entry is to be modified.
- The `-protocol` parameter specifies the protocol for which the QoS marking entry is to be modified. The `network qos-marking modify` man page describes the possible values of the protocol.
- The `-dscp` parameter specifies the Differentiated Services Code Point (DSCP) value. The possible values ranges from 0 through 63.
- The `-is-enabled` parameter is used to enable or disable the QoS marking for the specified protocol in the IPspace provided by the `-ipspace` parameter.

The following command enables the QoS marking for the NFS protocol in default IPspace:

```
network qos-marking modify -ipspace Default -protocol NFS -is-enabled true
```

The following command sets the DSCP value to 20 for the NFS protocol in the default IPspace:

```
network qos-marking modify -ipspace Default -protocol NFS -dscp 20
```

## Display QoS marking values

You can display the QoS marking values for different protocols, for each IPspace.

### Step

Display QoS marking values by using the `network qos-marking show` command.

The following command displays the QoS marking for all protocols in the default IPspace:

```

network qos-marking show -ipspace Default
IPspace Protocol DSCP Enabled?

Default
 CIFS 10 false
 FTP 48 false
 HTTP-admin 48 false
 HTTP-filesrv 10 false
 NDMP 10 false
 NFS 10 true
 SNMP 48 false
 SSH 48 false
 SnapMirror 10 false
 Telnet 48 false
 iSCSI 10 false
11 entries were displayed.

```

## Manage SNMP on the cluster (cluster administrators only)

### Overview

You can configure SNMP to monitor SVMs in your cluster to avoid issues before they occur, and to respond to issues if they do occur. Managing SNMP involves configuring SNMP users and configuring SNMP traphost destinations (management workstations) for all SNMP events. SNMP is disabled by default on data LIFs.

You can create and manage read-only SNMP users in the data SVM. Data LIFs must be configured to receive SNMP requests on the SVM.

SNMP network management workstations, or managers, can query the SVM SNMP agent for information. The SNMP agent gathers information and forwards it to the SNMP managers. The SNMP agent also generates trap notifications whenever specific events occur. The SNMP agent on the SVM has read-only privileges; it cannot be used for any set operations or for taking a corrective action in response to a trap. ONTAP provides an SNMP agent compatible with SNMP versions v1, v2c, and v3. SNMPv3 offers advanced security by using passphrases and encryption.

For more information about SNMP support in ONTAP systems, see [TR-4220: SNMP Support in Data ONTAP](#).

### What MIBs are

A MIB (Management Information Base) is a text file that describes SNMP objects and traps.

MIBs describe the structure of the management data of the storage system and they use a hierarchical namespace containing object identifiers (OIDs). Each OID identifies a variable that can be read by using SNMP.

Because MIBs are not configuration files and ONTAP does not read these files, SNMP functionality is not

affected by MIBs. ONTAP provides the following MIB file:

- A NetApp custom MIB (`netapp.mib`)

ONTAP supports IPv6 (RFC 2465), TCP (RFC 4022), UDP (RFC 4113), and ICMP (RFC 2466) MIBs, which show both IPv4 and IPv6 data, are supported.

ONTAP also provides a short cross-reference between object identifiers (OIDs) and object short names in the `traps.dat` file.

 The latest versions of the ONTAP MIBs and 'traps.dat' files are available on the NetApp Support Site. However, the versions of these files on the support site do not necessarily correspond to the SNMP capabilities of your ONTAP version. These files are provided to help you evaluate SNMP features in the latest ONTAP version.

## SNMP traps

SNMP traps capture system monitoring information that is sent as an asynchronous notification from the SNMP agent to the SNMP manager.

There are three types of SNMP traps: standard, built-in, and user-defined. User-defined traps are not supported in ONTAP.

A trap can be used to check periodically for operational thresholds or failures that are defined in the MIB. If a threshold is reached or a failure is detected, the SNMP agent sends a message (trap) to the traphosts alerting them of the event.

 ONTAP supports SNMPv1 traps and, starting in ONTAP 9.1, SNMPv3 traps. ONTAP does not support SNMPv2c traps and INFORMs.

### Standard SNMP traps

These traps are defined in RFC 1215. There are five standard SNMP traps that are supported by ONTAP: `coldStart`, `warmStart`, `linkDown`, `linkUp`, and `authenticationFailure`.

 The `authenticationFailure` trap is disabled by default. You must use the `system snmp authtrap` command to enable the trap. For more information, see the man pages: [ONTAP 9 commands](#)

### Built-in SNMP traps

Built-in traps are predefined in ONTAP and are automatically sent to the network management stations on the traphost list if an event occurs. These traps, such as `diskFailedShutdown`, `cpuTooBusy`, and `volumeNearlyFull`, are defined in the custom MIB.

Each built-in trap is identified by a unique trap code.

## Create an SNMP community and assigning it to a LIF

You can create an SNMP community that acts as an authentication mechanism between the management station and the storage virtual machine (SVM) when using SNMPv1 and SNMPv2c.

By creating SNMP communities in a data SVM, you can execute commands such as `snmpwalk` and `snmpget` on the data LIFs.

## About this task

- In new installations of ONTAP, SNMPv1 and SNMPv2c are disabled by default.
- SNMPv1 and SNMPv2c are enabled after you create an SNMP community.
- ONTAP supports read-only communities.
- By default, the "data" firewall policy that is assigned to data LIFs has SNMP service set to `deny`.

You must create a new firewall policy with SNMP service set to `allow` when creating an SNMP user for a data SVM.

Beginning with ONTAP 9.10.1, firewall policies are deprecated and wholly replaced with LIF service policies. For more information, see [Configure firewall policies for LIFs](#).

- You can create SNMP communities for SNMPv1 and SNMPv2c users for both the admin SVM and the data SVM.
- Because an SVM is not part of the SNMP standard, queries on data LIFs must include the NetApp root OID (1.3.6.1.4.1.789)—for example, `snmpwalk -v 2c -c snmpNFS 10.238.19.14 1.3.6.1.4.1.789`.

## Steps

1. Create an SNMP community by using the `system snmp community add` command. The following command shows how to create an SNMP community in the admin SVM cluster-1:

```
system snmp community add -type ro -community-name comty1 -vserver
cluster-1
```

The following command shows how to create an SNMP community in the data SVM vs1:

```
system snmp community add -type ro -community-name comty2 -vserver vs1
```

2. Verify that the communities have been created by using the `system snmp community show` command.

The following command shows the two communities created for SNMPv1 and SNMPv2c:

```
system snmp community show
cluster-1
rocomty1
vs1
rocomty2
```

3. Check whether SNMP is allowed as a service in the "data" firewall policy by using the `system services firewall policy show` command.

The following command shows that the snmp service is not allowed in the default "data" firewall policy (the snmp service is allowed in the "mgmt" firewall policy only):

```
system services firewall policy show
Vserver Policy Service Allowed

cluster-1
 data
 dns 0.0.0.0/0
 ndmp 0.0.0.0/0
 ndmps 0.0.0.0/0
cluster-1
 intercluster
 https 0.0.0.0/0
 ndmp 0.0.0.0/0
 ndmps 0.0.0.0/0
cluster-1
 mgmt
 dns 0.0.0.0/0
 http 0.0.0.0/0
 https 0.0.0.0/0
 ndmp 0.0.0.0/0
 ndmps 0.0.0.0/0
 ntp 0.0.0.0/0
 snmp 0.0.0.0/0
 ssh 0.0.0.0/0
```

4. Create a new firewall policy that allows access using the snmp service by using the system services firewall policy create command.

The following commands create a new data firewall policy named "data1" that allows the snmp

```
system services firewall policy create -policy data1 -service snmp
-vserver vs1 -allow-list 0.0.0.0/0

cluster-1::> system services firewall policy show -service snmp
Vserver Policy Service Allowed

vs1
 mgmt
 snmp 0.0.0.0/0
 data1
 snmp 0.0.0.0/0
```

5. Apply the firewall policy to a data LIF by using the `network interface modify` command with the -firewall-policy parameter.

The following command assigns the new "data1" firewall policy to LIF "datalif1":

```
network interface modify -vserver vs1 -lif datalif1 -firewall-policy
data1
```

## Configure SNMPv3 users in a cluster

SNMPv3 is a secure protocol when compared to SNMPv1 and SNMPv2c. To use SNMPv3, you must configure an SNMPv3 user to run the SNMP utilities from the SNMP manager.

### Step

Use the "security login create command" to create an SNMPv3 user.

You are prompted to provide the following information:

- Engine ID: Default and recommended value is local Engine ID
- Authentication protocol
- Authentication password
- Privacy protocol
- Privacy protocol password

### Result

The SNMPv3 user can log in from the SNMP manager by using the user name and password and run the SNMP utility commands.

### SNMPv3 security parameters

SNMPv3 includes an authentication feature that, when selected, requires users to enter their names, an authentication protocol, an authentication key, and their desired security level when invoking a command.

The following table lists the SNMPv3 security parameters :

| Parameter    | Command-line option             | Description                                                                 |
|--------------|---------------------------------|-----------------------------------------------------------------------------|
| engineID     | -e EngineID                     | Engine ID of the SNMP agent. Default value is local EngineID (recommended). |
| securityName | -u Name                         | User name must not exceed 32 characters.                                    |
| authProtocol | -a {none   MD5   SHA   SHA-256} | Authentication type can be none, MD5, SHA, or SHA-256.                      |
| authKey      | -A PASSPHRASE                   | Passphrase with a minimum of eight characters.                              |

|               |                                           |                                                                                                              |
|---------------|-------------------------------------------|--------------------------------------------------------------------------------------------------------------|
| securityLevel | -l {authNoPriv   AuthPriv   noAuthNoPriv} | Security level can be Authentication, No Privacy; Authentication, Privacy; or no Authentication, no Privacy. |
| privProtocol  | -x { none   des   aes128}                 | Privacy protocol can be none, des, or aes128                                                                 |
| privPassword  | -X password                               | Password with a minimum of eight characters.                                                                 |

### Examples for different security levels

This example shows how an SNMPv3 user created with different security levels can use the SNMP client-side commands, such as `snmpwalk`, to query the cluster objects.

For better performance, you should retrieve all objects in a table rather than a single object or a few objects from the table.

You must use `snmpwalk` 5.3.1 or later when the authentication protocol is SHA.

### Security level: authPriv

The following output shows the creation of an SNMPv3 user with the authPriv security level.

```
security login create -username snmpv3user -application snmp -authmethod usm
Enter the authoritative entity's EngineID [local EngineID]:
Which authentication protocol do you want to choose (none, md5, sha)
[none]:sha
```

### FIPS mode

```
Which authentication protocol do you want to choose (sha, sha2-256) [sha]

Enter authentication protocol password (minimum 8 characters long):
Enter authentication protocol password again:
Which privacy protocol do you want to choose (none, des) [none]: des
Enter privacy protocol password (minimum 8 characters long):
Enter privacy protocol password again:
```

### snmpwalk Test

The following output shows the SNMPv3 user running the `snmpwalk` command:

For better performance, you should retrieve all objects in a table rather than a single object or a few objects from the table.

```
$ snmpwalk -v 3 -u snmpv3user -a SHA -A password1! -x DES -X password1! -l authPriv 192.0.2.62 .1.3.6.1.4.1.789.1.5.8.1.2
Enterprises.789.1.5.8.1.2.1028 = "vo10"
Enterprises.789.1.5.8.1.2.1032 = "vo10"
Enterprises.789.1.5.8.1.2.1038 = "root_vs0"
Enterprises.789.1.5.8.1.2.1042 = "root_vstrap"
Enterprises.789.1.5.8.1.2.1064 = "vo11"
```

## Security level: authNoPriv

The following output shows the creation of an SNMPv3 user with the authNoPriv security level.

```
security login create -username snmpv3user1 -application snmp -authmethod usm -role admin
Enter the authoritative entity's EngineID [local EngineID]:
Which authentication protocol do you want to choose (none, md5, sha)
[none]: md5
```

## FIPS Mode

```
Which privacy protocol do you want to choose (aes128) [aes128]
Enter authentication protocol password (minimum 8 characters long):
Enter authentication protocol password again:
Which privacy protocol do you want to choose (none, des) [none]: none
```

## snmpwalk Test

The following output shows the SNMPv3 user running the snmpwalk command:

For better performance, you should retrieve all objects in a table rather than a single object or a few objects from the table.

```
$ snmpwalk -v 3 -u snmpv3user1 -a MD5 -A password1! -l authNoPriv
192.0.2.62 .1.3.6.1.4.1.789.1.5.8.1.2
Enterprises.789.1.5.8.1.2.1028 = "vo10"
Enterprises.789.1.5.8.1.2.1032 = "vo10"
Enterprises.789.1.5.8.1.2.1038 = "root_vs0"
Enterprises.789.1.5.8.1.2.1042 = "root_vstrap"
Enterprises.789.1.5.8.1.2.1064 = "vo11"
```

## Security level: noAuthNoPriv

The following output shows the creation of an SNMPv3 user with the noAuthNoPriv security level.

```
security login create -username snmpv3user2 -application snmp -authmethod usm -role admin
Enter the authoritative entity's EngineID [local EngineID]:
Which authentication protocol do you want to choose (none, md5, sha)
[none]: none
```

## FIPS Mode

FIPS will not allow you to choose none

## snmpwalk Test

The following output shows the SNMPv3 user running the snmpwalk command:

For better performance, you should retrieve all objects in a table rather than a single object or a few objects from the table.

```
$ snmpwalk -v 3 -u snmpv3user2 -l noAuthNoPriv 192.0.2.62
.1.3.6.1.4.1.789.1.5.8.1.2
Enterprises.789.1.5.8.1.2.1028 = "vol0"
Enterprises.789.1.5.8.1.2.1032 = "vol0"
Enterprises.789.1.5.8.1.2.1038 = "root_vs0"
Enterprises.789.1.5.8.1.2.1042 = "root_vstrap"
Enterprises.789.1.5.8.1.2.1064 = "vol1"
```

## Configure traphosts to receive SNMP notifications

You can configure the traphost (SNMP manager) to receive notifications (SNMP trap PDUs) when SNMP traps are generated in the cluster. You can specify either the host name or the IP address (IPv4 or IPv6) of the SNMP traphost.

### Before you begin

- SNMP and SNMP traps must be enabled on the cluster.

SNMP and SNMP traps are enabled by default.

- DNS must be configured on the cluster for resolving the traphost names.
- IPv6 must be enabled on the cluster to configure SNMP traphosts by using IPv6 addresses.
- For ONTAP 9.1 and later versions, you must have specified the authentication of a predefined User-based Security Model (USM) and privacy credentials when creating traphosts.

### Step

Add an SNMP traphost:

```
system snmp traphost add
```

Traps can be sent only when at least one SNMP management station is specified as a traphost.

The following command adds a new SNMPv3 traphost named `yyy.example.com` with a known USM user:

```
system snmp traphost add -peer-address yyy.example.com -usm-username
MyUsmUser
```

The following command adds a traphost using the IPv6 address of the host:

```
system snmp traphost add -peer-address 2001:0db8:1:1:209:6bff:feae:6d67
```

## Commands for managing SNMP

You can use the `system snmp` commands to manage SNMP, traps, and traphosts. You can use the `security` commands to manage SNMP users per SVM. You can use the `event` commands to manage events related to SNMP traps.

### Commands for configuring SNMP

| If you want to...           | Use this command...                                                                                                                                                                                                                                                |
|-----------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Enable SNMP on the cluster  | <code>options -option-name snmp.enable -option-value on</code><br><br>The SNMP service must be allowed under the management (mgmt) firewall policy. You can verify whether SNMP is allowed by using the <code>system services firewall policy show</code> command. |
| Disable SNMP on the cluster | <code>options -option-name snmp.enable -option-value off</code>                                                                                                                                                                                                    |

### Commands for managing SNMP v1, v2c, and v3 users

| If you want to...    | Use this command...                                                                    |
|----------------------|----------------------------------------------------------------------------------------|
| Configure SNMP users | <code>security login create</code>                                                     |
| Display SNMP users   | <code>security snmpusers</code> and <code>security login show -application snmp</code> |

|                                                                      |                       |
|----------------------------------------------------------------------|-----------------------|
| Delete SNMP users                                                    | security login delete |
| Modify the access-control role name of a login method for SNMP users | security login modify |

#### Commands for providing contact and location information

| If you want to...                                     | Use this command...  |
|-------------------------------------------------------|----------------------|
| Display or modify the contact details of the cluster  | system snmp contact  |
| Display or modify the location details of the cluster | system snmp location |

#### Commands for managing SNMP communities

| If you want to...                                                        | Use this command...          |
|--------------------------------------------------------------------------|------------------------------|
| Add a read-only (ro) community for an SVM or for all SVMs in the cluster | system snmp community add    |
| Delete a community or all communities                                    | system snmp community delete |
| Display the list of all communities                                      | system snmp community show   |

Because SVMs are not part of the SNMP standard, queries on data LIFs must include the NetApp root OID (1.3.6.1.4.1.789), for example, `snmpwalk -v 2c -c snmpNFS 10.238.19.14 1.3.6.1.4.1.789`.

#### Command for displaying SNMP option values

| If you want to...                                                                                                                                                                                                    | Use this command... |
|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------|
| Display the current values of all SNMP options, including cluster contact, contact location, whether the cluster is configured to send traps, the list of traphosts, and list of communities and access control type | system snmp show    |

#### Commands for managing SNMP traps and traphosts

| If you want to...                        | Use this command...      |
|------------------------------------------|--------------------------|
| Enable SNMP traps sent from the cluster  | system snmp init -init 1 |

## Manage routing in an SVM

### Overview

The routing table for an SVM determines the network path the SVM uses to communicate with a destination. It's important to understand how routing tables work so that you can prevent network problems before they occur.

Routing rules are as follows:

- ONTAP routes traffic over the most specific available route.
- ONTAP routes traffic over a default gateway route (having 0 bits of netmask) as a last resort, when more specific routes are not available.

In the case of routes with the same destination, netmask, and metric, there is no guarantee that the system will use the same route after a reboot or after an upgrade. This is especially an issue if you have configured multiple default routes.

It is a best practice to configure one default route only for an SVM. To avoid disruption, you should ensure that the default route is able to reach any network address that is not reachable by a more specific route. For more information, see the Knowledgebase article [SU134: Network access might be disrupted by incorrect routing configuration in clustered ONTAP](#)

## Create a static route

You can create static routes within a storage virtual machine (SVM) to control how LIFs use the network for outbound traffic.

When you create a route entry associated with an SVM, the route will be used by all LIFs that are owned by the specified SVM and that are on the same subnet as the gateway.

### Step

Use the `network route create` command to create a route.

```
network route create -vserver vs0 -destination 0.0.0.0/0 -gateway
10.61.208.1
```

## Enable multipath routing

If multiple routes have the same metric for a destination, only one of the routes is picked for outgoing traffic. This leads to other routes being unutilized for sending outgoing traffic. You can enable multipath routing to load balance and utilize all the available routes.

### Steps

1. Log in to the advanced privilege level:

```
set -privilege advanced
```

2. Enable multipath routing:

```
network options multipath-routing modify -is-enabled true
```

Multipath routing is enabled for all nodes in the cluster.

```
network options multipath-routing modify -is-enabled true
```

## Delete a static route

You can delete an unneeded static route from a storage virtual machine (SVM).

### Step

Use the `network route delete` command to delete a static route.

For more information about this command, see the `network route` man page: [ONTAP 9 commands](#).

The following example deletes a static route associated with SVM vs0 with a gateway of 10.63.0.1 and a

destination IP address of 0.0.0.0/0:

```
network route delete -vserver vs0 -gateway 10.63.0.1 -destination
0.0.0.0/0
```

## Display routing information

You can display information about the routing configuration for each SVM on your cluster. This can help you diagnose routing problems involving connectivity issues between client applications or services and a LIF on a node in the cluster.

### Steps

1. Use the `network route show` command to display routes within one or more SVMs. The following example shows a route configured in the vs0 SVM:

```
network route show
(network route show)
Vserver Destination Gateway Metric

vs0 0.0.0.0/0 172.17.178.1 20
```

2. Use the `network route show-lifs` command to display the association of routes and LIFs within one or more SVMs.

The following example shows LIFs with routes owned by the vs0 SVM:

```
network route show-lifs
(network route show-lifs)

Vserver: vs0
Destination Gateway Logical Interfaces

0.0.0.0/0 172.17.178.1 cluster_mgmt,
 LIF-b-01_mgmt1,
 LIF-b-02_mgmt1
```

3. Use the `network route active-entry show` command to display installed routes on one or more nodes, SVMs, subnets, or routes with specified destinations.

The following example shows all installed routes on a specific SVM:

```
network route active-entry show -vserver Data0
```

```

Vserver: Data0

## Remove dynamic routes from routing tables

When ICMP redirects are received for IPv4 and IPv6, dynamic routes are added to the routing table. By default, the dynamic routes are removed after 300 seconds. If you want to maintain dynamic routes for a different amount of time, you can change the time out value.

### About this task

You can set the timeout value from 0 to 65,535 seconds. If you set the value to 0, the routes never expire. Removing dynamic routes prevents loss of connectivity caused by the persistence of invalid routes.

### Steps

1. Display the current timeout value.

- For IPv4:

```
network tuning icmp show
```

- For IPv6:

```
network tuning icmp6 show
```

2. Modify the timeout value.

- For IPv4:

```
network tuning icmp modify -node node_name -redirect-timeout
timeout_value
```

- For IPv6:

```
network tuning icmp6 modify -node node_name -redirect-v6-timeout
timeout_value
```

3. Verify that the timeout value was modified correctly.

- For IPv4:

```
network tuning icmp show
```

- For IPv6:

```
network tuning icmp6 show
```

## ONTAP port usage on a storage system

### Overview

A number of well-known ports are reserved for ONTAP communications with specific services. Port conflicts will occur if a port value in your storage network environment is the same as on ONTAP port.

The following table lists the TCP ports and UDP ports that are used by ONTAP.

| Service      | Port/Protocol | Description                        |
|--------------|---------------|------------------------------------|
| ssh          | 22/TCP        | Secure shell login                 |
| telnet       | 23/TCP        | Remote login                       |
| DNS          | 53/TCP        | Load Balanced DNS                  |
| http         | 80/TCP        | Hyper Text Transfer Protocol       |
| rpcbind      | 111/TCP       | Remote procedure call              |
| rpcbind      | 111/UDP       | Remote procedure call              |
| ntp          | 123/UDP       | Network Time Protocol              |
| msrpc        | 135/UDP       | MSRPC                              |
| netbios-ssn  | 139/TCP       | NetBIOS service session            |
| snmp         | 161/UDP       | Simple network management protocol |
| https        | 443/TCP       | HTTP over TLS                      |
| microsoft-ds | 445/TCP       | Microsoft-ds                       |
| mount        | 635/TCP       | NFS mount                          |
| mount        | 635/UDP       | NFS Mount                          |
| named        | 953/UDP       | Name daemon                        |
| nfs          | 2049/UDP      | NFS Server daemon                  |
| nfs          | 2049/TCP      | NFS Server daemon                  |
| nrv          | 2050/TCP      | NetApp Remote Volume protocol      |
| iscsi        | 3260/TCP      | iSCSI target port                  |
| lockd        | 4045/TCP      | NFS lock daemon                    |
| lockd        | 4045/UDP      | NFS lock daemon                    |
| NSM          | 4046/TCP      | Network Status Monitor             |
| NSM          | 4046/UDP      | Network Status Monitor             |
| rquotad      | 4049/UDP      | NFS rquotad protocol               |
| krb524       | 4444/UDP      | Kerberos 524                       |
| mdns         | 5353/UDP      | Multicast DNS                      |

|                   |                   |                                        |
|-------------------|-------------------|----------------------------------------|
| HTTPS             | 5986/UDP          | HTTPS Port - Listening binary protocol |
| https             | 8443/TCP          | 7MTT GUI Tool through https            |
| ndmp              | 10000/TCP         | Network Data Management Protocol       |
| Cluster peering   | 11104/TCP         | Cluster peering                        |
| Cluster peering   | 11105/TCP         | Cluster peering                        |
| NDMP              | 18600 - 18699/TCP | NDMP                                   |
| cifs witness port | 40001/TCP         | cifs witness port                      |
| tls               | 50000/TCP         | Transport layer security               |
| iscsi             | 65200/TCP         | ISCSI port                             |

### ONTAP internal ports

The following table lists the TCP ports and UDP ports that are used internally by ONTAP. These ports are used to establish intracluster LIF communication:

| Port/Protocol | Description        |
|---------------|--------------------|
| 514           | Syslog             |
| 900           | NetApp Cluster RPC |
| 902           | NetApp Cluster RPC |
| 904           | NetApp Cluster RPC |
| 905           | NetApp Cluster RPC |
| 910           | NetApp Cluster RPC |
| 911           | NetApp Cluster RPC |
| 913           | NetApp Cluster RPC |
| 914           | NetApp Cluster RPC |
| 915           | NetApp Cluster RPC |
| 918           | NetApp Cluster RPC |
| 920           | NetApp Cluster RPC |
| 921           | NetApp Cluster RPC |
| 924           | NetApp Cluster RPC |
| 925           | NetApp Cluster RPC |
| 927           | NetApp Cluster RPC |
| 928           | NetApp Cluster RPC |
| 929           | NetApp Cluster RPC |
| 931           | NetApp Cluster RPC |
| 932           | NetApp Cluster RPC |

## View network information

### Overview

You can view information related to ports, LIFs, routes, failover rules, failover groups, firewall rules, DNS, NIS, and connections.

This information can be useful in situations such as reconfiguring networking settings, or when troubleshooting the cluster.

If you are a cluster administrator, you can view all the available networking information. If you are an SVM administrator, you can view only the information related to your assigned SVMs.

### Display network port information

You can display information about a specific port, or about all ports on all nodes in the cluster.

#### About this task

The following information is displayed:

- Node name
- Port name
- IPspace name
- Broadcast domain name
- Link status (up or down)
- MTU setting
- Port speed setting and operational status (1 gigabit or 10 gigabits per second)
- Auto-negotiation setting (true or false)
- Duplex mode and operational status (half or full)
- The port's interface group, if applicable
- The port's VLAN tag information, if applicable
- The port's health status (health or degraded)
- Reasons for a port being marked as degraded

If data for a field is not available (for example, the operational duplex and speed for an inactive port would not be available), the field value is listed as –.

## Step

Display network port information by using the `network port show` command.

You can display detailed information for each port by specifying the `-instance` parameter, or get specific information by specifying field names using the `-fields` parameter.

```
network port show
Node: node1

Ignore Speed (Mbps) Health
Health
Port IPspace Broadcast Domain Link MTU Admin/Oper Status
Status

## Display information about a VLAN (cluster administrators only)

You can display information about a specific VLAN or about all VLANs in the cluster.

### About this task

You can display detailed information for each VLAN by specifying the `-instance` parameter. You can display specific information by specifying field names using the `-fields` parameter.

### Step

Display information about VLANs by using the `network port vlan show` command. The following command displays information about all VLANs in the cluster:

```
network port vlan show
 Network Network
Node VLAN Name Port VLAN ID MAC Address
----- -----
cluster-1-01
 a0a-10 a0a 10 02:a0:98:06:10:b2
 a0a-20 a0a 20 02:a0:98:06:10:b2
 a0a-30 a0a 30 02:a0:98:06:10:b2
 a0a-40 a0a 40 02:a0:98:06:10:b2
 a0a-50 a0a 50 02:a0:98:06:10:b2
cluster-1-02
 a0a-10 a0a 10 02:a0:98:06:10:ca
 a0a-20 a0a 20 02:a0:98:06:10:ca
 a0a-30 a0a 30 02:a0:98:06:10:ca
 a0a-40 a0a 40 02:a0:98:06:10:ca
 a0a-50 a0a 50 02:a0:98:06:10:ca
```

## Display interface group information (cluster administrators only)

You can display information about an interface group to determine its configuration.

### About this task

The following information is displayed:

- Node on which the interface group is located
- List of network ports that are included in the interface group
- Interface group's name
- Distribution function (MAC, IP, port, or sequential)
- Interface group's Media Access Control (MAC) address
- Port activity status; that is, whether all aggregated ports are active (full participation), whether some are active (partial participation), or whether none are active

### Step

Display information about interface groups by using the `network port ifgrp show` command.

You can display detailed information for each node by specifying the `-instance` parameter. You can display specific information by specifying field names using the `-fields` parameter.

The following command displays information about all interface groups in the cluster:

| network port ifgrp show |            |                       |                   |              |          |
|-------------------------|------------|-----------------------|-------------------|--------------|----------|
| Node                    | Port IfGrp | Distribution Function | MAC Address       | Active Ports |          |
| cluster-1-01            | a0a        | ip                    | 02:a0:98:06:10:b2 | full         | e7a, e7b |
| cluster-1-02            | a0a        | sequential            | 02:a0:98:06:10:ca | full         | e7a, e7b |
| cluster-1-03            | a0a        | port                  | 02:a0:98:08:5b:66 | full         | e7a, e7b |
| cluster-1-04            | a0a        | mac                   | 02:a0:98:08:61:4e | full         | e7a, e7b |

The following command displays detailed interface group information for a single node:

```
network port ifgrp show -instance -node cluster-1-01

 Node: cluster-1-01
Interface Group Name: a0a
Distribution Function: ip
 Create Policy: multimode
 MAC Address: 02:a0:98:06:10:b2
Port Participation: full
 Network Ports: e7a, e7b
 Up Ports: e7a, e7b
 Down Ports: -
```

## Display LIF information

You can view detailed information about a LIF to determine its configuration.

You might also want to view this information to diagnose basic LIF problems, such as checking for duplicate IP addresses or verifying whether the network port belongs to the correct subnet. storage virtual machine (SVM) administrators can view only the information about the LIFs associated with the SVM.

### About this task

The following information is displayed:

- IP address associated with the LIF
- Administrative status of the LIF

- Operational status of the LIF

The operational status of data LIFs is determined by the status of the SVM with which the data LIFs are associated. When the SVM is stopped, the operational status of the LIF changes to down. When the SVM is started again, the operational status changes to up

- Node and the port on which the LIF resides

If data for a field is not available (for example, if there is no extended status information), the field value is listed as -.

### **Step**

Display LIF information by using the network interface show command.

You can view detailed information for each LIF by specifying the -instance parameter, or get specific information by specifying field names using the -fields parameter.

The following command displays general information about all LIFs in a cluster:

```

network interface show
 Logical Status Network Current Current Is
Vserver Interface Admin/Oper Address/Mask Node Port
Home

example
 lif1 up/up 192.0.2.129/22 node-01
 e0d
false
node
 cluster_mgmt up/up 192.0.2.3/20 node-02
 e0c
false
node-01
 clus1 up/up 192.0.2.65/18 node-01
 e0a
true
 clus2 up/up 192.0.2.66/18 node-01
 e0b
true
 mgmt1 up/up 192.0.2.1/20 node-01
 e0c
true
node-02
 clus1 up/up 192.0.2.67/18 node-02
 e0a
true
 clus2 up/up 192.0.2.68/18 node-02
 e0b
true
 mgmt2 up/up 192.0.2.2/20 node-02
 e0d
true
vs1
 d1 up/up 192.0.2.130/21 node-01
 e0d
false
 d2 up/up 192.0.2.131/21 node-01
 e0d
true
 data3 up/up 192.0.2.132/20 node-02
 e0c
true

```

The following command shows detailed information about a single LIF:

```
network interface show -lif data1 -instance

 Vserver Name: vs1
 Logical Interface Name: data1
 Role: data
 Data Protocol: nfs,cifs
 Home Node: node-01
 Home Port: e0c
 Current Node: node-03
 Current Port: e0c
 Operational Status: up
 Extended Status: -
 Is Home: false
 Network Address: 192.0.2.128
 Netmask: 255.255.192.0
 Bits in the Netmask: 18
 IPv4 Link Local: -
 Subnet Name: -
 Administrative Status: up
 Failover Policy: local-only
 Firewall Policy: data
 Auto Revert: false
 Fully Qualified DNS Zone Name: xxx.example.com
 DNS Query Listen Enable: false
 Failover Group Name: Default
 FCP WWPN: -
 Address family: ipv4
 Comment: -
 IPspace of LIF: Default
```

## Display routing information

You can display information about routes within an SVM.

### Step

Depending on the type of routing information that you want to view, enter the applicable command:

| To view information about... | Enter...                |
|------------------------------|-------------------------|
| Static routes, per SVM       | network route show      |
| LIFs on each route, per SVM  | network route show-lifs |

You can display detailed information for each route by specifying the `-instance` parameter. The following

command displays the static routes within the SVMs in cluster-1:

```
network route show
Vserver Destination Gateway Metric

Cluster
cluster-1 0.0.0.0/0 10.63.0.1 10
vs1 0.0.0.0/0 198.51.9.1 10
vs3 0.0.0.0/0 192.0.2.1 20
```

The following command displays the association of static routes and logical interfaces (LIFs) within all SVMs in cluster-1:

```
network route show-lifs
Vserver: Cluster
Destination Gateway Logical Interfaces

0.0.0.0/0 10.63.0.1 -
Vserver: cluster-1
Destination Gateway Logical Interfaces

0.0.0.0/0 198.51.9.1 cluster_mgmt,
 cluster-1_mgmt1,
Vserver: vs1
Destination Gateway Logical Interfaces

0.0.0.0/0 192.0.2.1 data1_1, data1_2
Vserver: vs3
Destination Gateway Logical Interfaces

0.0.0.0/0 192.0.2.1 data2_1, data2_2
```

#### Display DNS host table entries (cluster administrators only)

The DNS host table entries map host names to IP addresses. You can display the host names and alias names and the IP address that they map to for all SVMs in a cluster.

#### Step

Display the host name entries for all SVMs by using the vserver services name-service dns hosts show command.

The following example displays the host table entries:

```
vserver services name-service dns hosts show
Vserver Address Hostname Aliases
----- ----- -----
cluster-1 10.72.219.36 lnx219-36 -
vs1 10.72.219.37 lnx219-37 lnx219-37.example.com
```

You can use the vserver services name-service dns command to enable DNS on an SVM, and configure it to use DNS for host-name resolution. Host names are resolved using external DNS servers.

### Display DNS domain configurations

You can display the DNS domain configuration of one or more storage virtual machines (SVMs) in your cluster to verify that it is configured properly.

#### Step

Viewing the DNS domain configurations by using the vserver services name-service dns show command.

The following command displays the DNS configurations for all SVMs in the cluster:

```
vserver services name-service dns show
 Name
Vserver State Domains Servers
----- -----
cluster-1 enabled xyz.company.com 192.56.0.129,
 192.56.0.130
vs1 enabled xyz.company.com 192.56.0.129,
 192.56.0.130
vs2 enabled xyz.company.com 192.56.0.129,
 192.56.0.130
vs3 enabled xyz.company.com 192.56.0.129,
 192.56.0.130
```

The following command displays detailed DNS configuration information for SVM vs1:

```
vserver services name-service dns show -vserver vs1
 Vserver: vs1
 Domains: xyz.company.com
 Name Servers: 192.56.0.129, 192.56.0.130
 Enable/Disable DNS: enabled
 Timeout (secs): 2
 Maximum Attempts: 1
```

## Display information about failover groups

You can view information about failover groups, including the list of nodes and ports in each failover group, whether failover is enabled or disabled, and the type of failover policy that is being applied to each LIF.

### Steps

1. Display the target ports for each failover group by using the `network interface failover-groups show` command.

The following command displays information about all failover groups on a two-node cluster:

```
network interface failover-groups show
 Failover
Vserver Group Targets

Cluster
 Cluster
 cluster1-01:e0a, cluster1-01:e0b,
 cluster1-02:e0a, cluster1-02:e0b
vs1
 Default
 cluster1-01:e0c, cluster1-01:e0d,
 cluster1-01:e0e, cluster1-02:e0c,
 cluster1-02:e0d, cluster1-02:e0e
```

2. Display the target ports and broadcast domain for a specific failover group by using the `network interface failover-groups show` command.

The following command displays detailed information about failover group data12 for SVM vs4:

```

network interface failover-groups show -vserver vs4 -failover-group
data12

 Vserver Name: vs4
 Failover Group Name: data12
 Failover Targets: cluster1-01:e0f, cluster1-01:e0g, cluster1-02:e0f,
 cluster1-02:e0g
 Broadcast Domain: Default

```

3. Display the failover settings used by all LIFs by using the `network interface show` command.

The following command displays the failover policy and failover group that is being used by each LIF:

| vserver  | lif                | failover-policy       | failover-group |
|----------|--------------------|-----------------------|----------------|
| Cluster  | cluster1-01_clus_1 | local-only            | Cluster        |
| Cluster  | cluster1-01_clus_2 | local-only            | Cluster        |
| Cluster  | cluster1-02_clus_1 | local-only            | Cluster        |
| Cluster  | cluster1-02_clus_2 | local-only            | Cluster        |
| cluster1 | cluster_mgmt       | broadcast-domain-wide | Default        |
| cluster1 | cluster1-01_mgmt1  | local-only            | Default        |
| cluster1 | cluster1-02_mgmt1  | local-only            | Default        |
| vs1      | data1              | disabled              | Default        |
| vs3      | data2              | system-defined        | group2         |

## Display LIF failover targets

You might have to check whether the failover policies and the failover groups of a LIF are configured correctly. To prevent misconfiguration of the failover rules, you can display the failover targets for a single LIF or for all LIFs.

### About this task

Displaying LIF failover targets enables you to check for the following:

- Whether the LIFs are configured with the correct failover group and failover policy
- Whether the resulting list of failover target ports is appropriate for each LIF
- Whether the failover target of a data LIF is not a management port (e0M)

### Step

Display the failover targets of a LIF by using the `failover` option of the `network interface show` command.

The following command displays information about the failover targets for all LIFs in a two-node cluster. The

Failover Targets row shows the (prioritized) list of node-port combinations for a given LIF.

```
network interface show -failover
 Logical Home Failover Failover
Vserver Interface Node:Port Policy Group

Cluster
 node1_clus1 node1:e0a local-only Cluster
 Failover Targets: node1:e0a,
 node1:e0b
 node1_clus2 node1:e0b local-only Cluster
 Failover Targets: node1:e0b,
 node1:e0a
 node2_clus1 node2:e0a local-only Cluster
 Failover Targets: node2:e0a,
 node2:e0b
 node2_clus2 node2:e0b local-only Cluster
 Failover Targets: node2:e0b,
 node2:e0a
cluster1
 cluster_mgmt node1:e0c broadcast-domain-wide
 Default
 Failover Targets: node1:e0c,
 node1:e0d,
 node2:e0c,
 node2:e0d
 node1_mgmt1 node1:e0c local-only Default
 Failover Targets: node1:e0c,
 node1:e0d
 node2_mgmt1 node2:e0c local-only Default
 Failover Targets: node2:e0c,
 node2:e0d
vs1
 data1 node1:e0e system-defined bcast1
 Failover Targets: node1:e0e,
 node1:e0f,
 node2:e0e,
 node2:e0f
```

## Display LIFs in a load balancing zone

You can verify whether a load balancing zone is configured correctly by displaying all of the LIFs that belong to it. You can also view the load balancing zone of a particular LIF, or the load balancing zones for all LIFs.

### Step

Display the LIFs and load balancing details that you want by using one of the following commands

| To display...                               | Enter...                                                                                                            |
|---------------------------------------------|---------------------------------------------------------------------------------------------------------------------|
| LIFs in a particular load balancing zone    | <code>network interface show -dns-zone zone_name</code><br>zone_name specifies the name of the load balancing zone. |
| The load balancing zone of a particular LIF | <code>network interface show -lif lif_name -fields dns-zone</code>                                                  |
| The load balancing zones of all LIFs        | <code>network interface show -fields dns-zone</code>                                                                |

#### Examples of displaying load balancing zones for LIFs

The following command displays the details of all LIFs in the load balancing zone storage.company.com for SVM vs0:

```
net int show -vserver vs0 -dns-zone storage.company.com

 Logical Status Network Current Current Is
Vserver Interface Admin/Oper Address/Mask Node Port Home

vs0
 lif3 up/up 10.98.226.225/20 ndeux-11 e0c true
 lif4 up/up 10.98.224.23/20 ndeux-21 e0c true
 lif5 up/up 10.98.239.65/20 ndeux-11 e0c true
 lif6 up/up 10.98.239.66/20 ndeux-11 e0c true
 lif7 up/up 10.98.239.63/20 ndeux-21 e0c true
 lif8 up/up 10.98.239.64/20 ndeux-21 e0c true
```

The following command displays the DNS zone details of the LIF data3:

```
network interface show -lif data3 -fields dns-zone
Vserver lif dns-zone

vs0 data3 storage.company.com
```

The following command displays the list of all LIFs in the cluster and their corresponding DNS zones:

```
network interface show -fields dns-zone
Vserver lif dns-zone

cluster cluster_mgmt none
ndeux-21 clus1 none
ndeux-21 clus2 none
ndeux-21 mgmt1 none
vs0 data1 storage.company.com
vs0 data2 storage.company.com
```

## Display cluster connections

You can display all the active connections in the cluster or a count of active connections on the node by client, logical interface, protocol, or service. You can also display all the listening connections in the cluster.

### Display active connections by client (cluster administrators only)

You can view the active connections by client to verify the node that a specific client is using and to view possible imbalances between client counts per node.

#### About this task

The count of active connections by client is useful in the following scenarios:

- Finding a busy or overloaded node.
- Determining why a particular client's access to a volume is slow.

You can view details about the node that the client is accessing and then compare it with the node on which the volume resides. If accessing the volume requires traversing the cluster network, clients might experience decreased performance because of the remote access to the volume on an oversubscribed remote node.

- Verifying that all nodes are being used equally for data access.
- Finding clients that have an unexpectedly high number of connections.
- Verifying whether certain clients have connections to a node.

#### Step

Display a count of the active connections by client on a node by using the `network connections active show-clients` command.

For more information about this command, see the man page: [ONTAP 9 commands](#)

| network connections active show-clients |              |                      |       |
|-----------------------------------------|--------------|----------------------|-------|
| Node                                    | Vserver Name | Client IP Address    | Count |
| node0                                   | vs0          | 192.0.2.253          | 1     |
|                                         | vs0          | 192.0.2.252          | 2     |
|                                         | Cluster      | 192.10.2.124         | 5     |
| node1                                   | vs0          | 192.0.2.250          | 1     |
|                                         | vs0          | 192.0.2.252          | 3     |
|                                         | Cluster      | 192.10.2.123         | 4     |
| node2                                   | vs1          | customer.example.com | 1     |
|                                         | vs1          | 192.0.2.245          | 3     |
|                                         | Cluster      | 192.10.2.122         | 4     |
| node3                                   | vs1          | customer.example.org | 1     |
|                                         | vs1          | customer.example.net | 3     |
|                                         | Cluster      | 192.10.2.121         | 4     |

#### Display active connections by protocol (cluster administrators only)

You can display a count of the active connections by protocol (TCP or UDP) on a node to compare the usage of protocols within the cluster.

#### About this task

The count of active connections by protocol is useful in the following scenarios:

- Finding the UDP clients that are losing their connection.

If a node is near its connection limit, UDP clients are the first to be dropped.

- Verifying that no other protocols are being used.

#### Step

Display a count of the active connections by protocol on a node by using the `network connections active show-protocols` command.

For more information about this command, see the man page.

```

network connections active show-protocols
Node Vserver Name Protocol Count
----- ----- ----- -----
node0
 vs0 UDP 19
 Cluster TCP 11
node1
 vs0 UDP 17
 Cluster TCP 8
node2
 vs1 UDP 14
 Cluster TCP 10
node3
 vs1 UDP 18
 Cluster TCP 4

```

#### **Display active connections by service (cluster administrators only)**

You can display a count of the active connections by service type (for example, by NFS, SMB, mount, and so on) for each node in a cluster. This is useful to compare the usage of services within the cluster, which helps to determine the primary workload of a node.

#### **About this task**

The count of active connections by service is useful in the following scenarios:

- Verifying that all nodes are being used for the appropriate services and that the load balancing for that service is working.
- Verifying that no other services are being used. Display a count of the active connections by service on a node by using the `network connections active show-services` command.

For more information about this command, see the man page: [ONTAP 9 commands](#)

| network connections active show-services |              |          |       |
|------------------------------------------|--------------|----------|-------|
| Node                                     | Vserver Name | Service  | Count |
| node0                                    |              |          |       |
|                                          | vs0          | mount    | 3     |
|                                          | vs0          | nfs      | 14    |
|                                          | vs0          | nlm_v4   | 4     |
|                                          | vs0          | cifs_srv | 3     |
|                                          | vs0          | port_map | 18    |
|                                          | vs0          | rclopcp  | 27    |
|                                          | Cluster      | ctlopcp  | 60    |
| node1                                    |              |          |       |
|                                          | vs0          | cifs_srv | 3     |
|                                          | vs0          | rclopcp  | 16    |
|                                          | Cluster      | ctlopcp  | 60    |
| node2                                    |              |          |       |
|                                          | vs1          | rclopcp  | 13    |
|                                          | Cluster      | ctlopcp  | 60    |
| node3                                    |              |          |       |
|                                          | vs1          | cifs_srv | 1     |
|                                          | vs1          | rclopcp  | 17    |
|                                          | Cluster      | ctlopcp  | 60    |

### Display active connections by LIF on a node and SVM

You can display a count of active connections for each LIF, by node and storage virtual machine (SVM), to view connection imbalances between LIFs within the cluster.

#### About this task

The count of active connections by LIF is useful in the following scenarios:

- Finding an overloaded LIF by comparing the number of connections on each LIF.
- Verifying that DNS load balancing is working for all data LIFs.
- Comparing the number of connections to the various SVMs to find the SVMs that are used the most.

#### Step

Display a count of active connections for each LIF by SVM and node by using the `network connections active show-lifs` command.

For more information about this command, see the man page: [ONTAP 9 commands](#)

| network connections active show-lifs |              |                |       |  |
|--------------------------------------|--------------|----------------|-------|--|
| Node                                 | Vserver Name | Interface Name | Count |  |
| node0                                |              |                |       |  |
|                                      | vs0          | dataif1        | 3     |  |
|                                      | Cluster      | node0_clus_1   | 6     |  |
|                                      | Cluster      | node0_clus_2   | 5     |  |
| node1                                |              |                |       |  |
|                                      | vs0          | dataif2        | 3     |  |
|                                      | Cluster      | node1_clus_1   | 3     |  |
|                                      | Cluster      | node1_clus_2   | 5     |  |
| node2                                |              |                |       |  |
|                                      | vs1          | dataif2        | 1     |  |
|                                      | Cluster      | node2_clus_1   | 5     |  |
|                                      | Cluster      | node2_clus_2   | 3     |  |
| node3                                |              |                |       |  |
|                                      | vs1          | dataif1        | 1     |  |
|                                      | Cluster      | node3_clus_1   | 2     |  |
|                                      | Cluster      | node3_clus_2   | 2     |  |

#### Display active connections in a cluster

You can display information about the active connections in a cluster to view the LIF, port, remote host, service, storage virtual machines (SVMs), and protocol used by individual connections.

#### About this task

Viewing the active connections in a cluster is useful in the following scenarios:

- Verifying that individual clients are using the correct protocol and service on the correct node.
- If a client is having trouble accessing data using a certain combination of node, protocol, and service, you can use this command to find a similar client for configuration or packet trace comparison.

#### Step

Display the active connections in a cluster by using the `network connections active show` command.

For more information about this command, see the man page: [ONTAP 9 commands](#)

The following command shows the active connections on the node node1:

```

network connections active show -node node1
Vserver Interface Remote
Name Name:Local Port Host:Port Protocol/Service

Node: node1
Cluster node1_clus_1:50297 192.0.2.253:7700 TCP/ctlopcp
Cluster node1_clus_1:13387 192.0.2.253:7700 TCP/ctlopcp
Cluster node1_clus_1:8340 192.0.2.252:7700 TCP/ctlopcp
Cluster node1_clus_1:42766 192.0.2.252:7700 TCP/ctlopcp
Cluster node1_clus_1:36119 192.0.2.250:7700 TCP/ctlopcp
vs1 data1:111 host1.aa.com:10741 UDP/port-map
vs3 data2:111 host1.aa.com:10741 UDP/port-map
vs1 data1:111 host1.aa.com:12017 UDP/port-map
vs3 data2:111 host1.aa.com:12017 UDP/port-map

```

The following command shows the active connections on SVM vs1:

```

network connections active show -vserver vs1
Vserver Interface Remote
Name Name:Local Port Host:Port Protocol/Service

Node: node1
vs1 data1:111 host1.aa.com:10741 UDP/port-map
vs1 data1:111 host1.aa.com:12017 UDP/port-map

```

### Display listening connections in a cluster

You can display information about the listening connections in a cluster to view the LIFs and ports that are accepting connections for a given protocol and service.

#### About this task

Viewing the listening connections in a cluster is useful in the following scenarios:

- Verifying that the desired protocol or service is listening on a LIF if client connections to that LIF fail consistently.
- Verifying that a UDP/rcllopcp listener is opened at each cluster LIF if remote data access to a volume on one node through a LIF on another node fails.
- Verifying that a UDP/rcllopcp listener is opened at each cluster LIF if SnapMirror transfers between two nodes in the same cluster fail.
- Verifying that a TCP/ctlopcp listener is opened at each intercluster LIF if SnapMirror transfers between two nodes in different clusters fail.

#### Step

Display the listening connections per node by using the `network connections listening show` command.

| network connections listening show |                           |                  |
|------------------------------------|---------------------------|------------------|
| Vserver Name                       | Interface Name:Local Port | Protocol/Service |
| Node: node0                        |                           |                  |
| Cluster                            | node0_clus_1:7700         | TCP/ctlopcp      |
| vs1                                | data1:4049                | UDP/unknown      |
| vs1                                | data1:111                 | TCP/port-map     |
| vs1                                | data1:111                 | UDP/port-map     |
| vs1                                | data1:4046                | TCP/sm           |
| vs1                                | data1:4046                | UDP/sm           |
| vs1                                | data1:4045                | TCP/nlm-v4       |
| vs1                                | data1:4045                | UDP/nlm-v4       |
| vs1                                | data1:2049                | TCP/nfs          |
| vs1                                | data1:2049                | UDP/nfs          |
| vs1                                | data1:635                 | TCP/mount        |
| vs1                                | data1:635                 | UDP/mount        |
| Cluster                            | node0_clus_2:7700         | TCP/ctlopcp      |

### Commands for diagnosing network problems

You can diagnose problems on your network by using commands such as `ping`, `traceroute`, `ndp`, and `tcpdump`. You can also use commands such as `ping6` and `traceroute6` to diagnose IPv6 problems.

| If you want to...                                                                                                                                              | Enter this command...                                                                                                  |
|----------------------------------------------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------|
| Test whether the node can reach other hosts on your network                                                                                                    | <code>network ping</code>                                                                                              |
| Test whether the node can reach other hosts on your IPv6 network                                                                                               | <code>network ping6</code>                                                                                             |
| Trace the route that the IPv4 packets take to a network node                                                                                                   | <code>network traceroute</code>                                                                                        |
| Trace the route that the IPv6 packets take to a network node                                                                                                   | <code>network traceroute6</code>                                                                                       |
| Manage the Neighbor Discovery Protocol (NDP)                                                                                                                   | <code>network ndp</code>                                                                                               |
| Display statistics about packets that are received and sent on a specified network interface or on all network interfaces                                      | <code>run -node node_name ifstat</code><br><br><b>Note:</b> This command is available from the nodeshell.              |
| Display information about neighboring devices that are discovered from each node and port in the cluster, including the remote device type and device platform | <code>network device-discovery show</code>                                                                             |
| View the CDP neighbors of the node (ONTAP supports only CDPv1 advertisements)                                                                                  | <code>run -node node_name cdpd show-neighbors</code><br><br><b>Note:</b> This command is available from the nodeshell. |

|                                                                           |                                                                                                                                                                                                                                                                                                                                                                                                          |
|---------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

## Display network connectivity with neighbor discovery protocols

In a data center, you can use neighbor discovery protocols to view network connectivity between a pair of physical or virtual systems and their network interfaces. ONTAP supports two neighbor discovery protocols: Cisco Discovery Protocol (CDP) and Link Layer Discovery Protocol (LLDP).

### About this task

Neighbor discovery protocols enable you to automatically discover and view information about directly connected protocol-enabled devices in a network. Each device advertises identification, capabilities, and connectivity information. This information is transmitted in Ethernet frames to a multicast MAC address and is received by all neighboring protocol-enabled devices.

For two devices to become neighbors, each must have a protocol enabled and correctly configured. Discovery protocol functionality is limited to directly connected networks. Neighbors can include protocol-enabled devices such as switches, routers, bridges, and so on. ONTAP supports two neighbor discovery protocols, which can be used individually or together.

### Cisco Discovery Protocol (CDP)

CDP is a proprietary link layer protocol developed by Cisco Systems. It is enabled by default in ONTAP for cluster ports, but must be enabled explicitly for data ports.

### Link Layer Discovery Protocol (LLDP)

LLDP is a vendor-neutral protocol specified in the standards document IEEE 802.1AB. It must be enabled explicitly for all ports.

### Use CDP to detect network connectivity

Using CDP to detect network connectivity consists of reviewing deployment considerations, enabling it on data ports, viewing neighbor devices, and adjusting CDP configuration values as needed. CDP is enabled by default on cluster ports.

CDP must also be enabled on any switches and routers before information about neighbor devices can be

displayed.

| ONTAP release      | Description                                                                                                                             |
|--------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| 9.10.1 and earlier | CDP is also used by the cluster switch health monitor to automatically discover your cluster and management network switches.           |
| 9.11.1 and later   | CDP is also used by the cluster switch health monitor to automatically discover your cluster, storage, and management network switches. |

[System administration](#)

### Considerations for using CDP

By default, CDP-compliant devices send CDPv2 advertisements. CDP-compliant devices send CDPv1 advertisements only when they receive CDPv1 advertisements. ONTAP supports only CDPv1. Therefore, when an ONTAP node sends CDPv1 advertisements, CDP-compliant neighboring devices send back CDPv1 advertisements.

You should consider the following information before enabling CDP on a node:

- CDP is supported for all ports.
- CDP advertisements are sent and received by ports that are in the up state.
- CDP must be enabled on both the transmitting and receiving devices for sending and receiving CDP advertisements.
- CDP advertisements are sent at regular intervals, and you can configure the time interval.
- When IP addresses are changed for a LIF, the node sends the updated information in the next CDP advertisement.
- ONTAP 9.10.1 and earlier:
  - CDP is always enabled on cluster ports.
  - CDP is disabled, by default, on all non-cluster ports.
- ONTAP 9.11.1 and later:
  - CDP is always enabled on cluster and storage ports.
  - CDP is disabled, by default, on all non-cluster and non-storage ports.

Sometimes when LIFs are changed on the node, the CDP information is not updated at the receiving device side (for example, a switch). If you encounter such a problem, you should configure the network interface of the node to the down status and then to the up status.

- Only IPv4 addresses are advertised in CDP advertisements.
- For physical network ports with VLANs, all of the LIFs configured on the VLANs on that port are advertised.
- For physical ports that are part of an interface group, all of the IP addresses configured on that interface group are advertised on each physical port.
- For an interface group that hosts VLANs, all of the LIFs configured on the interface group and the VLANs are advertised on each of the network ports.

- Due to CDP packets being restricted to no more than 1500 bytes, on ports configured with a large number of LIFs only a subset of these IP addresses may be reported on the adjacent switch.

## Enable or disable CDP

To discover and send advertisements to CDP-compliant neighboring devices, CDP must be enabled on each node of the cluster.

By default in ONTAP 9.10.1 and earlier, CDP is enabled on all cluster ports of a node and disabled on all non-cluster ports of a node.

By default in ONTAP 9.11.1 and later, CDP is enabled on all cluster and storage ports of a node and disabled on all non-cluster and non-storage ports of a node.

### About this task

The `cdpd.enable` option controls whether CDP is enabled or disabled on the ports of a node:

- For ONTAP 9.10.1 and earlier, `on` enables CDP on non-cluster ports.
- For ONTAP 9.11.1 and later, `on` enables CDP on non-cluster and non-storage ports.
- For ONTAP 9.10.1 and earlier, `off` disables CDP on non-cluster ports; you cannot disable CDP on cluster ports.
- For ONTAP 9.11.1 and later, `off` disables CDP on non-cluster and non-storage ports; you cannot disable CDP on cluster ports.

When CDP is disabled on a port that is connected to a CDP-compliant device, network traffic might not be optimized.

### Steps

1. Display the current CDP setting for a node, or for all nodes in a cluster:

| To view the CDP setting of... | Enter...                                                       |
|-------------------------------|----------------------------------------------------------------|
| A node                        | <code>run - node &lt;node_name&gt; options cdःpd.enable</code> |
| All nodes in a cluster        | <code>options cdःpd.enable</code>                              |

2. Enable or disable CDP on all ports of a node, or on all ports of all nodes in a cluster:

| To enable or disable CDP on... | Enter...                                                          |
|--------------------------------|-------------------------------------------------------------------|
| A node                         | <code>run -node node_name options cdःpd.enable {on or off}</code> |
| All nodes in a cluster         | <code>options cdःpd.enable {on or off}</code>                     |

## **View CDP neighbor information**

You can view information about the neighboring devices that are connected to each port of the nodes of your cluster, provided that the port is connected to a CDP-compliant device. You can use the `network device-discovery show -protocol cdp` command to view neighbor information.

### **About this task**

In ONTAP 9.10.1 and earlier, because CDP is always enabled for cluster ports, CDP neighbor information is always displayed for those ports. CDP must be enabled on non-cluster ports for neighbor information to appear for those ports.

In ONTAP 9.11.1 and later, because CDP is always enabled for cluster and storage ports, CDP neighbor information is always displayed for those ports. CDP must be enabled on non-cluster and non-storage ports for neighbor information to appear for those ports.

### **Step**

Display information about all CDP-compliant devices that are connected to the ports on a node in the cluster:

```
network device-discovery show -node node -protocol cdp
```

The following command shows the neighbors that are connected to the ports on node sti2650-212:

```
network device-discovery show -node sti2650-212 -protocol cdp
Node/ Local Discovered
Protocol Port Device (LLDP: ChassisID) Interface Platform
----- ----- -----
----- -----
sti2650-212/cdp

 e0f RTP-LF349-510K33.gdl.eng.netapp.com(FDO21521S4T)
 Ethernet1/24 N9K-
C93180YC-FX
```

The output lists the Cisco devices that are connected to each port of the specified node.

## Configure the hold time for CDP messages

Hold time is the period of time for which CDP advertisements are stored in cache in neighboring CDP-compliant devices. Hold time is advertised in each CDPv1 packet and is updated whenever a CDPv1 packet is received by a node.

- The value of the `cdpd.holdtime` option should be set to the same value on both nodes of an HA pair.
- The default hold time value is 180 seconds, but you can enter values ranging from 10 seconds to 255 seconds.
- If an IP address is removed before the hold time expires, the CDP information is cached until the hold time expires.

### Steps

1. Display the current CDP hold time for a node, or for all nodes in a cluster:

| To view the hold time of... | Enter...                                                |
|-----------------------------|---------------------------------------------------------|
| A node                      | <code>run -node node_name options cdःpd.holdtime</code> |
| All nodes in a cluster      | <code>options cdःpd.holdtime</code>                     |

2. Configure the CDP hold time on all ports of a node, or on all ports of all nodes in a cluster:

| To set the hold time on... | Enter...                                                         |
|----------------------------|------------------------------------------------------------------|
| A node                     | <code>run -node node_name options cdःpd.holdtime holdtime</code> |
| All nodes in a cluster     | <code>options cdःpd.holdtime holdtime</code>                     |

## Set the interval for sending CDP advertisements

CDP advertisements are sent to CDP neighbors at periodic intervals. You can increase or decrease the interval for sending CDP advertisements depending on network traffic and changes in the network topology.

- The value of the `cdpd.interval` option should be set to the same value on both nodes of an HA pair.
- The default interval is 60 seconds, but you can enter a value from 5 seconds to 900 seconds.

### Steps

1. Display the current CDP advertisement time interval for a node, or for all nodes in a cluster:

| To view the interval for... | Enter...                                                |
|-----------------------------|---------------------------------------------------------|
| A node                      | <code>run -node node_name options cdःpd.interval</code> |
| All nodes in a cluster      | <code>options cdःpd.interval</code>                     |

2. Configure the interval for sending CDP advertisements for all ports of a node, or for all ports of all nodes in a cluster:

| To set the interval for... | Enter...                                           |
|----------------------------|----------------------------------------------------|
| A node                     | run -node node_name options cdpd.interval interval |
| All nodes in a cluster     | options cdpd.interval interval                     |

## View or clear CDP statistics

You can view the CDP statistics for the cluster and non-cluster ports on each node to detect potential network connectivity issues. CDP statistics are cumulative from the time they were last cleared.

### About this task

In ONTAP 9.10.1 and earlier, because CDP is always enabled for ports, CDP statistics are always displayed for traffic on those ports. CDP must be enabled on ports for statistics to appear for those ports.

In ONTAP 9.11.1 and later, because CDP is always enabled for cluster and storage ports, CDP statistics are always displayed for traffic on those ports. CDP must be enabled on non-cluster or non-storage ports for statistics to appear for those ports.

### Step

Display or clear the current CDP statistics for all ports on a node:

| If you want to...        | Enter...                            |
|--------------------------|-------------------------------------|
| View the CDP statistics  | run -node node_name cdpd show-stats |
| Clear the CDP statistics | run -node node_name cdpd zero-stats |

## Example of showing and clearing statistics

The following command shows the CDP statistics before they are cleared. The output displays the total number of packets that have been sent and received since the last time the statistics were cleared.

```
run -node node1 cdpd show-stats

RECEIVE
 Packets: 9116 | Csum Errors: 0 | Unsupported Vers: 4561
 Invalid length: 0 | Malformed: 0 | Mem alloc fails: 0
 Missing TLVs: 0 | Cache overflow: 0 | Other errors: 0

TRANSMIT
 Packets: 4557 | Xmit fails: 0 | No hostname: 0
 Packet truncated: 0 | Mem alloc fails: 0 | Other errors: 0

OTHER
 Init failures: 0
```

The following command clears the CDP statistics:

```
run -node node1 cdpd zero-stats
```

```
run -node node1 cdpd show-stats
```

RECEIVE

|                 |   |                 |   |                   |   |
|-----------------|---|-----------------|---|-------------------|---|
| Packets:        | 0 | Csum Errors:    | 0 | Unsupported Vers: | 0 |
| Invalid length: | 0 | Malformed:      | 0 | Mem alloc fails:  | 0 |
| Missing TLVs:   | 0 | Cache overflow: | 0 | Other errors:     | 0 |

TRANSMIT

|                   |   |                  |   |               |   |
|-------------------|---|------------------|---|---------------|---|
| Packets:          | 0 | Xmit fails:      | 0 | No hostname:  | 0 |
| Packet truncated: | 0 | Mem alloc fails: | 0 | Other errors: | 0 |

OTHER

|                |   |
|----------------|---|
| Init failures: | 0 |
|----------------|---|

After the statistics are cleared, they begin to accumulate after the next CDP advertisement is sent or received.

### Use LLDP to detect network connectivity

Using LLDP to detect network connectivity consists of reviewing deployment considerations, enabling it on all ports, viewing neighbor devices, and adjusting LLDP configuration values as needed.

LLDP must also be enabled on any switches and routers before information about neighbor devices can be displayed.

ONTAP currently reports the following type-length-value structures (TLVs):

- Chassis ID
- Port ID
- Time-To-Live (TTL)
- System name

The system name TLV is not sent on CNA devices.

Certain converged network adapters (CNAs), such as the X1143 adapter and the UTA2 onboard ports, contain offload support for LLDP:

- LLDP offload is used for Data Center Bridging (DCB).
- Displayed information might differ between the cluster and the switch.

The Chassis ID and Port ID data displayed by the switch might be different for CNA and non-CNA ports.

For example:

- For non-CNA ports:
  - Chassis ID is a fixed MAC address of one of the ports on the node
  - Port ID is the port name of the respective port on the node
- For CNA ports:
  - Chassis ID and Port ID are the MAC addresses of the respective ports on the node.

However, the data displayed by the cluster is consistent for these port types.

The LLDP specification defines access to the collected information through an SNMP MIB. However, ONTAP does not currently support the LLDP MIB.

## Enable or disable LLDP

To discover and send advertisements to LLDP-compliant neighboring devices, LLDP must be enabled on each node of the cluster. Beginning with ONTAP 9.7, LLDP is enabled on all ports of a node by default.

### About this task

For ONTAP 9.10.1 and earlier, the `lldp.enable` option controls whether LLDP is enabled or disabled on the ports of a node:

- `on` enables LLDP on all ports.
- `off` disables LLDP on all ports.

For ONTAP 9.11.1 and later, the `lldp.enable` option controls whether LLDP is enabled or disabled on the non-cluster and non-storage ports of a node:

- `on` enables LLDP on all non-cluster and non-storage ports.
- `off` disables LLDP on all non-cluster and non-storage ports.

### Steps

1. Display the current LLDP setting for a node, or for all nodes in a cluster:

- Single node: `run -node node_name options lldp.enable`
- All nodes: `options lldp.enable`

2. Enable or disable LLDP on all ports of a node, or on all ports of all nodes in a cluster:

| To enable or disable LLDP on... | Enter...                                                      |
|---------------------------------|---------------------------------------------------------------|
| A node                          | <code>run -node node_name options lldp.enable {on off}</code> |
| All nodes in a cluster          | <code>options lldp.enable {on off}</code>                     |

- Single node:

```
run -node node_name options lldp.enable {on|off}
```

- All nodes:

```
options lldp.enable {on|off}
```

## View LLDP neighbor information

You can view information about the neighboring devices that are connected to each port of the nodes of your cluster, provided that the port is connected to an LLDP-compliant device. You use the network device-discovery show command to view neighbor information.

### Step

1. Display information about all LLDP-compliant devices that are connected to the ports on a node in the cluster:

```
network device-discovery show -node node -protocol lldp
```

The following command shows the neighbors that are connected to the ports on node cluster-1\_01. The output lists the LLDP-enabled devices that are connected to each port of the specified node. If the –protocol option is omitted, the output also lists CDP-enabled devices.

```
network device-discovery show -node cluster-1_01 -protocol lldp
Node/ Local Discovered
Protocol Port Device Interface Platform
----- ----- -----
----- -----
cluster-1_01/lldp
 e2a 0013.c31e.5c60 GigabitEthernet1/36
 e2b 0013.c31e.5c60 GigabitEthernet1/35
 e2c 0013.c31e.5c60 GigabitEthernet1/34
 e2d 0013.c31e.5c60 GigabitEthernet1/33
```

## Adjust the interval for transmitting LLDP advertisements

LLDP advertisements are sent to LLDP neighbors at periodic intervals. You can increase or decrease the interval for sending LLDP advertisements depending on network traffic and changes in the network topology.

### About this task

The default interval recommended by IEEE is 30 seconds, but you can enter a value from 5 seconds to 300 seconds.

### Steps

1. Display the current LLDP advertisement time interval for a node, or for all nodes in a cluster:

- Single node:

```
run -node <node_name> options lldp.xmit.interval
```

- All nodes:

```
options lldp.xmit.interval
```

## 2. Adjust the interval for sending LLDP advertisements for all ports of a node, or for all ports of all nodes in a cluster:

- Single node:

```
run -node <node_name> options lldp.xmit.interval <interval>
```

- All nodes:

```
options lldp.xmit.interval <interval>
```

## Adjust the time-to-live value for LLDP advertisements

Time-To-Live (TTL) is the period of time for which LLDP advertisements are stored in cache in neighboring LLDP-compliant devices. TTL is advertised in each LLDP packet and is updated whenever an LLDP packet is received by a node. TTL can be modified in outgoing LLDP frames.

### About this task

- TTL is a calculated value, the product of the transmit interval (`lldp.xmit.interval`) and the hold multiplier (`lldp.xmit.hold`) plus one.
- The default hold multiplier value is 4, but you can enter values ranging from 1 to 100.
- The default TTL is therefore 121 seconds, as recommended by IEEE, but by adjusting the transmit interval and hold multiplier values, you can specify a value for outgoing frames from 6 seconds to 30001 seconds.
- If an IP address is removed before the TTL expires, the LLDP information is cached until the TTL expires.

### Steps

#### 1. Display the current hold multiplier value for a node, or for all nodes in a cluster:

- Single node:

```
run -node <node_name> options lldp.xmit.hold
```

- All nodes:

```
options lldp.xmit.hold
```

2. Adjust the hold multiplier value on all ports of a node, or on all ports of all nodes in a cluster:

- Single node:

```
run -node <node_name> options lldp.xmit.hold <hold_value>
```

- All nodes:

```
options lldp.xmit.hold <hold_value>
```

## View or clear LLDP statistics

You can view the LLDP statistics for the cluster and non-cluster ports on each node to detect potential network connectivity issues. LLDP statistics are cumulative from the time they were last cleared.

### About this task

For ONTAP 9.10.1 and earlier, because LLDP is always enabled for cluster ports, LLDP statistics are always displayed for traffic on those ports. LLDP must be enabled on non-cluster ports for statistics to appear for those ports.

For ONTAP 9.11.1 and later, because LLDP is always enabled for cluster and storage ports, LLDP statistics are always displayed for traffic on those ports. LLDP must be enabled on non-cluster and non-storage ports for statistics to appear for those ports.

### Step

Display or clear the current LLDP statistics for all ports on a node:

| If you want to...         | Enter...                          |
|---------------------------|-----------------------------------|
| View the LLDP statistics  | run -node node_name lldp stats    |
| Clear the LLDP statistics | run -node node_name lldp stats -z |

### Show and clear statistics example

The following command shows the LLDP statistics before they are cleared. The output displays the total number of packets that have been sent and received since the last time the statistics were cleared.

```
cluster-1::> run -node vsim1 lldp stats

RECEIVE
 Total frames: 190k | Accepted frames: 190k | Total drops:
 0

TRANSMIT
 Total frames: 5195 | Total failures: 0

OTHER
 Stored entries: 64
```

The following command clears the LLDP statistics.

```
cluster-1::> The following command clears the LLDP statistics:
run -node vsim1 lldp stats -z
run -node node1 lldp stats

RECEIVE
 Total frames: 0 | Accepted frames: 0 | Total drops:
 0

TRANSMIT
 Total frames: 0 | Total failures: 0

OTHER
 Stored entries: 64
```

After the statistics are cleared, they begin to accumulate after the next LLDP advertisement is sent or received.

# NAS storage management

## Manage NAS protocols with System Manager

### NAS management overview with System Manager

The topics in this section show you how to configure and manage NAS environments with System Manager in ONTAP 9.7 and later releases.

If you are using the classic System Manager (available only in ONTAP 9.7 and earlier), see these topics:

- [NFS configuration overview](#)
- [SMB configuration overview](#)

System Manager supports workflows for:

- Initial configuration of clusters that you intend to use for NAS file services.
- Additional volume provisioning for changing storage needs.
- Configuration and maintenance for industry-standard authentication and security facilities.

Using System Manager, you can manage NAS services at the component level:

- Protocols – NFS, SMB, or both (NAS multiprotocol)
- Name services – DNS, LDAP, and NIS
- Name service switch
- Kerberos security
- Exports and shares
- Qtrees
- Name mapping of users and groups

### Provision NFS storage for VMware datastores

Before using Virtual Storage Console for VMware vSphere (VSC) to provision NFS volumes on an ONTAP based storage system for ESXi hosts, enable NFS using System Manager for ONTAP 9.7 or later.

After creating an [NFS-enabled storage VM](#) in System Manager, you then provision NFS volumes and manage datastores using VSC.

Beginning with VSC 7.0, VSC is part of the [ONTAP Tools for VMware vSphere virtual appliance](#), which includes VSC, vStorage APIs for Storage Awareness (VASA) Provider, and Storage Replication Adapter (SRA) for VMware vSphere capabilities.

Be sure to check the [NetApp Interoperability Matrix](#) to confirm compatibility between your current ONTAP and VSC releases.

To set up NFS access for ESXi hosts to datastores using System Manager Classic (for ONTAP 9.7 and earlier releases), see [NFS configuration for ESXi using VSC overview](#)

For more information, see [TR-4597: VMware vSphere for ONTAP](#) and the documentation for your VSC release.

## Provision NAS storage for home directories

Create volumes to provide storage for home directories using the SMB protocol.

This procedure creates new volumes for home directories on an [existing SMB-enabled storage VM](#). You can accept system defaults when configuring volumes or specify custom configurations.

You can create FlexVol volumes, or for large file systems with high performance requirements, you can create FlexGroup volumes. See also [Provision NAS storage for large file systems using FlexGroup volumes](#).

You can also save the specifications of this volume to an Ansible Playbook. For more details, go to [Use Ansible Playbooks to add or edit volumes or LUNs](#).

### Steps

1. Add a new volume in an SMB-enabled storage VM.
  - a. Select **Storage > Volumes** and then click **Add**.
  - b. Enter a name, select the storage VM, and enter a size.

Only storage VMs configured with the SMB protocol are listed. If only one storage VM configured with the SMB protocol is available, the **Storage VM** field is not shown.

- If you click **Save** at this point, System Manager uses system defaults to create and add a FlexVol volume.
- You can click **More options** to customize the configuration of the volume to enable services such as authorization, quality of service, and data protection. Refer to [Customize the volume configuration](#), then return here to complete the following steps.

2. Click **Storage > Shares**, click **Add**, and select **Home Directory**.
3. On a Windows client, do the following to verify that the share is accessible.
  - a. In Windows Explorer, map a drive to the share in the following format:  
\\\_SMB\_Server\_Name\_\_Share\_Name\_
  - If the share name was created with variables (%w, %d, or %u), be sure to test access with a resolved name.
  - b. On the newly created drive, create a test file, and then delete the file.

### Customize the volume configuration

You can customize the volume configuration when you add volumes instead of accepting the system defaults.

## Procedure

After clicking **More options**, select the functionality you need and enter the required values.

- Cache for remote volume.
- Performance service level (quality of service, QoS).

Beginning with ONTAP 9.8, you can specify a custom QoS policy or disable QoS, in addition to the default Value selection.

- To disable QoS, select **Custom, Existing**, then **none**.
- If you select **Custom** and specify an existing service level, a local tier is automatically chosen.
- Beginning with ONTAP 9.9.1, if you choose to create a custom performance service level, you can use System Manager to manually select the local tier (**Manual placement**) on which you want to place the volume you are creating.

This option is not available if you select the remote cache or FlexGroup volume options.

- FlexGroup volumes (select **Distribute volume data across the cluster**).

This option is not available if you previously selected **Manual placement** under **Performance Service Level**. Otherwise, the volume you are adding becomes a FlexVol volume by default.

- Access permissions for the protocols for which the volume is configured.
- Data protection with SnapMirror (local or remote), then specify the protection policy and settings for the destination cluster from the pull-down lists.
- Click **Save** to create the volume and add it to the cluster and storage VM.

After you save the volume, return to [Step 2 in the workflow](#) to complete provisioning for home directories.

## Provision NAS storage for Linux servers using NFS

Create volumes to provide storage for Linux servers using the NFS protocol with ONTAP System Manager (9.7 and later).

This procedure creates new volumes on an [existing NFS-enabled storage VM](#). You can accept system defaults when configuring volumes or specify custom configurations.

You can create FlexVol volumes, or for large file systems with high performance requirements, you can create FlexGroup volumes. See also [Provision NAS storage for large file systems using FlexGroup volumes](#).

You can also save the specifications of this volume to an Ansible Playbook. For more details, go to [Use Ansible Playbooks to add or edit volumes or LUNs](#).

If you want details about the range of ONTAP NFS protocol capabilities, consult the [NFS reference overview](#).

## Steps

1. Add a new volume in an NFS-enabled storage VM.
  - a. Click **Storage > Volumes** and then click **Add**.
  - b. Enter a name, select the storage VM, and enter a size.

Only storage VMs configured with the NFS protocol are listed. If only one storage VM configured with the SMB protocol is available, the **Storage VM** field is not shown.

- If you click **Save** at this point, System Manager uses system defaults to create and add a FlexVol volume.

The default export policy grants full access to all users.

- You can click **More options** to customize the configuration of the volume to enable services such as authorization, quality of service, and data protection. Refer to [Customize the volume configuration](#), then return here to complete the following steps.

## 2. On a Linux client, do the following to verify access.

a. Create and mount the volume using the network interface of the storage VM.

b. On the newly mounted volume, create a test file, write text to it, and then delete the file.

After verifying access, you can [restrict client access with the volume's export policy](#) and set any desired UNIX ownership and permissions on the mounted volume.

## Customize the volume configuration

You can customize the volume configuration when you add volumes instead of accepting the system defaults.

### Procedure

After clicking **More options**, select the functionality you need and enter the required values.

- Cache for remote volume.
- Performance service level (quality of service, QoS).

Beginning with ONTAP 9.8, you can specify a custom QoS policy or disable QoS, in addition to the default Value selection.

- To disable QoS, select **Custom, Existing**, then **none**.
- If you select **Custom** and specify an existing service level, a local tier is automatically chosen.
- Beginning with ONTAP 9.9.1, if you choose to create a custom performance service level, you can use System Manager to manually select the local tier (**Manual placement**) on which you want to place the volume you are creating.

This option is not available if you select the remote cache or FlexGroup volume options.

- FlexGroup volumes (select **Distribute volume data across the cluster**).

This option is not available if you previously selected **Manual placement** under **Performance Service Level**. Otherwise, the volume you are adding becomes a FlexVol volume by default.

- Access permissions for the protocols for which the volume is configured.
- Data protection with SnapMirror (local or remote), then specify the protection policy and settings for the destination cluster from the pull-down lists.
- Click **Save** to create the volume and add it to the cluster and storage VM.

After you save the volume, return to [Step 2](#) in the workflow to complete provisioning for Linux servers using NFS.

## Other ways to do this in ONTAP

| To perform this task with...                   | Refer to...                                             |
|------------------------------------------------|---------------------------------------------------------|
| System Manager Classic (ONTAP 9.7 and earlier) | <a href="#">NFS configuration overview</a>              |
| The ONTAP command line interface (CLI)         | <a href="#">NFS configuration overview with the CLI</a> |

## Manage access using export policies

Enable Linux client access to NFS servers by using export policies.

This procedure creates or modifies export policies for an [existing NFS-enabled storage VM](#).

### Steps

1. In System Manager, Click **Storage > Volumes**.
2. Click an NFS-enabled volume and click **More**.
3. Click **Edit Export Policy** and then click **Select an existing policy** or **Add a new policy**.

## Provision NAS storage for Windows servers using SMB

Create volumes to provide storage for Windows servers using the SMB protocol using System Manager, which is available with ONTAP 9.7 and later.

This procedure creates new volumes on an [existing SMB-enabled storage VM](#) and creates a share for the volume root (/) directory. You can accept systems defaults when configuring volumes or specify custom configurations. After initial SMB configuration, you can also create additional shares and modify their properties.

You can create FlexVol volumes, or for large file systems with high performance requirements, you can create FlexGroup volumes. See also [Provision NAS storage for large file systems using FlexGroup volumes](#).

You can also save the specifications of this volume to an Ansible Playbook. For more details, go to [Use Ansible Playbooks to add or edit volumes or LUNs](#).

If you want details about the range of ONTAP SMB protocol capabilities, consult the [SMB reference overview](#).

### Before you begin

- Beginning in ONTAP 9.13.1, you can enable capacity analytics and Activity Tracking by default on new volumes. In System Manager, you can manage default settings at the cluster or storage VM level. For more information see [Enable File System Analytics](#).

### Steps

1. Add a new volume in an SMB-enabled storage VM.
  - a. Click **Storage > Volumes** and then click **Add**.
  - b. Enter a name, select the storage VM, and enter a size.

Only storage VMs configured with the SMB protocol are listed. If only one storage VM configured with

the SMB protocol is available, the **Storage VM** field is not shown.

- If you select **Save** at this point, System Manager uses system defaults to create and add a FlexVol volume.
- You can select **More options** to customize the configuration of the volume to enable services such as authorization, quality of service, and data protection. Refer to [Customize the volume configuration](#), then return here to complete the following steps.

## 2. Switch to a Windows client to verify that the share is accessible.

- a. In Windows Explorer, map a drive to the share in the following format:

`\_\_SMB\_Server\_Name\_\_Share\_Name\_\_`

- b. On the newly created drive, create a test file, write text to it, and then delete the file.

After verifying access, you can restrict client access with the share ACL and set any desired security properties on the mapped drive. See [Create an SMB share](#) for more information.

## Add or modify shares

You can add additional shares after initial SMB configuration. Shares are created with default values and properties you select. These can be modified later.

You can set the following share properties when configuring a share:

- Access permissions
- Share properties
  - Enable continuous availability to shares that contain Hyper-V and SQL Server over SMB data (beginning with ONTAP 9.10.1). See also:
    - [Continuously available share requirements for Hyper-V over SMB](#)
    - [Continuously available share requirements for SQL Server over SMB](#)
  - Encrypt data with SMB 3.0 while accessing this share.

After initial configuration, you can also modify these properties:

- Symbolic links
  - Enable or disable symlinks and widelinks
- Share properties
  - Allow clients to access Snapshot copies directory.
  - Enable oplocks, allowing clients to lock files and cache content locally (default).
  - Enable access-based enumeration (ABE) to display shared resources based on the access permissions of the user.

## Procedures

To add a new share in an SMB-enabled volume, click **Storage > Shares**, click **Add**, and select **Share**.

To modify an existing share, click **Storage > Shares**, then click the  and select **Edit**.

## Customize the volume configuration

You can customize the volume configuration when you add volumes instead of accepting the system defaults.

## Procedure

After clicking **More options**, select the functionality you need and enter the required values.

- Cache for remote volume.
- Performance service level (quality of service, QoS).

Beginning with ONTAP 9.8 you can specify a Custom QoS policy or disable QoS, in addition to the default value selection.

- To disable QoS, select **Custom, Existing**, then **none**.
- If you select **Custom** and specify an existing service level, a local tier is automatically chosen.
- Beginning with ONTAP 9.9.1, if you choose to create a custom performance service level, you can use System Manager to manually select the local tier (**Manual placement**) on which you want to place the volume you are creating.

This option is not available if you select the remote cache or FlexGroup volume options.

- FlexGroup volumes (select **Distribute volume data across the cluster**).

This option is not available if you previously selected **Manual placement** under **Performance Service Level**. Otherwise, the volume you are adding becomes a FlexVol volume by default.

**This option is not available if you previously selected \*Manual placement under Performance Service Level.** Otherwise, the volume you are adding becomes a FlexVol volume by default.

**Access permission for the protocols for which the volume is configured.**

**\*Data protection with SnapMirror (local or remote), then specify the protection policy and settings for the destination cluster from the pull-down lists.**

**\*Click \*Save to create the volume and add it to the cluster and storage VM.**

You can customize the volume configuration when you add volumes instead of accepting the system defaults.

## Procedure

After clicking **More options**, select the functionality you need and enter the required values.

- Cache for remote volume.
- Performance service level (quality of service, QoS).

Beginning with ONTAP 9.8, you can specify a custom QoS policy or disable QoS, in addition to the default Value selection.

- To disable QoS, select **Custom, Existing**, then **none**.
- If you select **Custom** and specify an existing service level, a local tier is automatically chosen.
- Beginning with ONTAP 9.9.1, if you choose to create a custom performance service level, you can use System Manager to manually select the local tier (**Manual placement**) on which you want to place the volume you are creating.

This option is not available if you select the remote cache or FlexGroup volume options.

- FlexGroup volumes (select **Distribute volume data across the cluster**).

This option is not available if you previously selected **Manual placement** under **Performance Service Level**. Otherwise, the volume you are adding becomes a FlexVol volume by default.

- Access permissions for the protocols for which the volume is configured.
- Data protection with SnapMirror (local or remote), then specify the protection policy and settings for the destination cluster from the pull-down lists.
- Click **Save** to create the volume and add it to the cluster and storage VM.

After you save the volume, return to [Step 2 in the workflow](#) to complete provisioning for Windows servers using SMB.

## Other ways to do this in ONTAP

| To perform this task with...                   | Refer to...                                             |

## Provision NAS storage for both Windows and Linux using both NFS and SMB

Create volumes to provide storage for clients using either the NFS or SMB protocol.

This procedure creates new volumes on an [existing storage VM enabled for both NFS and SMB protocols](#).

You can create FlexVol volumes, or for large file systems with high performance requirements, you can create FlexGroup volumes. See also [Provision NAS storage for large file systems using FlexGroup volumes](#).

You can also save the specifications of this volume to an Ansible Playbook. For more details, go to [Use Ansible Playbooks to add or edit volumes or LUNs](#).

### Steps

1. Add a new volume in a storage VM enabled for both NFS and SMB.
  - a. Click **Storage > Volumes** and then click **Add**.
  - b. Enter a name, select the storage VM, and enter a size. Only storage VMs configured with both the NFS and SMB protocols are listed. If only one storage VM configured with the NFS and SMB protocols is available, the **Storage VM** field is not shown.
  - c. Click **More Options** and select **Share via NFS**.
 

The default setting grants full access to all users. You can add more restrictive rules to the export policy later.
  - d. Select **Share via SMB**.
 

The share is created with a default Access Control List (ACL) set to "Full Control" for the **Everyone** group. You can add restrictions to the ACL later.
  - e. If you click **Save** at this point, System Manager uses system defaults to create and add a FlexVol volume.

Alternatively, you can continue to enable any additional required services such as authorization, quality of service, and data protection. Refer to [Customize the volume configuration](#), then return here to complete the following steps.

2. On a Linux client, verify that the export is accessible.
  - a. Create and mount the volume using the network interface of the storage VM.
  - b. On the newly mounted volume, create a test file, write text to it, and then delete the file.
3. On a Windows client, do the following to verify that the share is accessible.
  - a. In Windows Explorer, map a drive to the share in the following format:  
\\\_SMB\_Server\_Name\_\_Share\_Name\_
  - b. On the newly created drive, create a test file, write text to it, and then delete the file.

After verifying access, you can [restrict client access with the volume's export policy](#), [restrict client access with the share ACL](#), and set any desired ownership and permissions on the exported and shared volume.

## Customize the volume configuration

You can customize the volume configuration when you add volumes instead of accepting the system defaults.

### Procedure

After clicking **More options**, select the functionality you need and enter the required values.

- Cache for remote volume.
- Performance service level (quality of service, QoS).

Beginning with ONTAP 9.8, you can specify a custom QoS policy or disable QoS, in addition to the default Value selection.

- To disable QoS, select **Custom, Existing**, then **none**.
- If you select **Custom** and specify an existing service level, a local tier is automatically chosen.
- Beginning with ONTAP 9.9.1, if you choose to create a custom performance service level, you can use System Manager to manually select the local tier (**Manual placement**) on which you want to place the volume you are creating.

This option is not available if you select the remote cache or FlexGroup volume options.

- FlexGroup volumes (select **Distribute volume data across the cluster**).

This option is not available if you previously selected **Manual placement** under **Performance Service Level**. Otherwise, the volume you are adding becomes a FlexVol volume by default.

- Access permissions for the protocols for which the volume is configured.
- Data protection with SnapMirror (local or remote), then specify the protection policy and settings for the destination cluster from the pull-down lists.
- Click **Save** to create the volume and add it to the cluster and storage VM.

After you save the volume, return to [Step 2 in the workflow](#) to complete multiprotocol provisioning for Windows and Linux servers.

## Other ways to do this in ONTAP

| To perform these tasks with...                 | See this content...                                                                                                                                                                                                                                                                 |

| The ONTAP command line interface               | <a href="#">SMB configuration overview with the CLI</a><br><a href="#">NFS configuration overview with the CLI</a><br><a href="#">What the security styles and their effects are</a><br><a href="#">Case-sensitivity of file and directory names in a multiprotocol environment</a> |

## Secure client access with Kerberos

Enable Kerberos to secure storage access for NAS clients.

This procedure configures Kerberos on an existing storage VM enabled for [NFS](#) or [SMB](#).

Before beginning you should have configured DNS, NTP, and [LDAP](#) on the storage system.

### Steps

1. At the ONTAP command line, set UNIX permissions for the storage VM root volume.
  - a. Display the relevant permissions on the storage VM root volume: `volume show -volume root_vol_name-fields user,group,unix-permissions`

The root volume of the storage VM must have the following configuration:

| Name...          | Setting...   |
|------------------|--------------|
| UID              | root or ID 0 |
| GID              | root or ID 0 |
| UNIX permissions | 755          |

- b. If these values are not shown, use the `volume modify` command to update them.
2. Set user permissions for the storage VM root volume.
  - a. Display the local UNIX users: `vserver services name-service unix-user show -vserver vserver_name`

The storage VM should have the following UNIX users configured:

| User name | User ID | Primary group ID |
|-----------|---------|------------------|
| nfs       | 500     | 0                |
| root      | 0       | 0                |

**Note:** The NFS user is not required if a Kerberos-UNIX name mapping exists for the SPN of the NFS

- client user; see step 5.
- If these values are not shown, use the `vserver services name-service unix-user modify` command to update them.
  - Set group permissions for the storage VM root volume.
    - Display the local UNIX groups: `vserver services name-service unix-group show -vserver vserver_name`

The storage VM should have the following UNIX groups configured:

| Group name | Group ID |
|------------|----------|
| daemon     | 1        |
| root       | 0        |

- If these values are not shown, use the `vserver services name-service unix-group modify` command to update them.
- Switch to System Manager to configure Kerberos
- In System Manager, click **Storage > Storage VMs** and select the storage VM.
- Click **Settings**.
- Click under Kerberos.
- Click **Add** under Kerberos Realm, and complete the following sections:
  - Add Kerberos Realm
 

Enter configuration details depending on KDC vendor.

    - Add Network Interface to Realm
 

Click **Add** and select a network interface.
- If desired, add mappings from Kerberos principal names to local user names.
  - Click **Storage > Storage VMs** and select the storage VM.
  - Click **Settings**, and then click under **Name Mapping**.
  - Under **Kerberos to UNIX**, add patterns and replacements using regular expressions.

## Provide client access with name services

Enable ONTAP to look up host, user, group, or netgroup information using LDAP or NIS to authenticate NAS clients.

This procedure creates or modifies LDAP or NIS configurations on an existing storage VM enabled for [NFS](#) or [SMB](#).

For LDAP configurations, you should have the LDAP configuration details required in your environment and you should be using a default ONTAP LDAP schema.

### Steps

- Configure the required service: click **Storage > Storage VMs**.

2. Select the storage VM, click **Settings**, and then click for LDAP or NIS.
3. Include any changes in the name services switch: click under Name Services Switch.

## Manage directories and files

Expand the System Manager volume display to view and delete directories and files.

Beginning with ONTAP 9.9.1, directories are deleted with low-latency fast directory delete functionality.

For more information about viewing file systems in ONTAP 9.9.1 and later, see [File System Analytics overview](#).

### Step

1. Select **Storage > Volumes**. Expand a volume to view its contents.

## Manage host-specific users and groups with System Manager

Beginning with ONTAP 9.10.1, you can use System Manager to manage users and groups that are specific to a UNIX or Windows host.

You can perform the following procedures:

| Windows                                                                                                                                                                                                 | UNIX                                                                                                                                                                                           |
|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <ul style="list-style-type: none"><li><a href="#">View Windows users and groups</a></li><li><a href="#">Add, edit, or delete a Windows group</a></li><li><a href="#">Manage Windows Users</a></li></ul> | <ul style="list-style-type: none"><li><a href="#">View UNIX users and groups</a></li><li><a href="#">Add, edit, or delete a UNIX group</a></li><li><a href="#">Manage UNIX Users</a></li></ul> |

### View Windows users and groups

In System Manager, you can view a list of Windows users and groups.

### Steps

1. In System Manager, click **Storage > Storage VMs**.
2. Select the storage VM, then select the **Settings** tab.
3. Scroll to the **Host Users and Groups** area.

The **Windows** section displays a summary of the number of users in each group associated with the selected storage VM.

4. Click in the **Windows** section.
5. Click the **Groups** tab, then click next to a group name to view details about that group.
6. To view the users in a group, select the group, then click the **Users** tab.

### Add, edit, or delete a Windows group

In System Manager, you can manage Windows groups by adding, editing, or deleting them.

### Steps

1. In System Manager, view the list of Windows groups. Refer to [View Windows users and groups](#).
2. On the **Groups** tab, you can manage groups with the following tasks:

| To perform this action... | Perform these steps...                                                                                                                                                                                                                                                                                                                                                                                                                          |
|---------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Add a group               | <ol style="list-style-type: none"> <li>1. Click  <b>Add</b>.</li> <li>2. Enter the group information.</li> <li>3. Specify privileges.</li> <li>4. Specify group members (add local users, domain users, or domain groups).</li> </ol>                                                                                                                          |
| Edit a group              | <ol style="list-style-type: none"> <li>1. Next to the group name, click  , then click <b>Edit</b>.</li> <li>2. Modify the group information.</li> </ol>                                                                                                                                                                                                      |
| Delete a group            | <ol style="list-style-type: none"> <li>1. Check the box next to the group or groups you want to delete.</li> <li>2. Click  <b>Delete</b>.</li> </ol> <p><b>Note:</b> You can also delete a single group by clicking  next to the group name, then clicking <b>Delete</b>.</p> |

## Manage Windows Users

In System Manager, you can manage Windows users by adding, editing, deleting, enabling, or disabling them. You can also change the password of a Windows user.

### Steps

1. In System Manager, view the list of users for the group. Refer to [View Windows users and groups](#).
2. On the **Users** tab, you can manage users with the following tasks:

| To perform this action... | Perform these steps...                                                                                                                                                                                                                     |
|---------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Add a user                | <ol style="list-style-type: none"> <li>1. Click  <b>Add</b>.</li> <li>2. Enter the user information.</li> </ol>                                         |
| Edit a user               | <ol style="list-style-type: none"> <li>1. Next to the user name, click  , then click <b>Edit</b>.</li> <li>2. Modify the user information.</li> </ol> |

|                      |                                                                                                                                                                                                                                                                                                                                                                                                                                       |

| Delete a user        | <ol style="list-style-type: none"> <li>Check the box next to the user or users you want to delete.</li> <li>Click  <b>Delete</b>.</li> </ol> <p><b>Note:</b> You can also delete a single user by clicking  next to the user name, then clicking <b>Delete</b>.</p> |
| Change user password | <ol style="list-style-type: none"> <li>Next to the user name, click , then click <b>Change Password</b>.</li> <li>Enter the new password and confirm it.</li> </ol>                                                                                                                                                                                |
| Enable a user        | <ol style="list-style-type: none"> <li>Check the box next to each disabled user you want to enable.</li> <li>Click  <b>Enable</b>.</li> </ol>                                                                                                                                                                                                        |
| Disable a users      | <ol style="list-style-type: none"> <li>Check the box next to each enabled user you want to disable.</li> <li>Click  <b>Disable</b>.</li> </ol>                                                                                                                                                                                                       |

## View UNIX users and groups

In System Manager, you can view a list of UNIX users and groups.

### Steps

- In System Manager, click **Storage > Storage VMs**.
- Select the storage VM, then select the **Settings** tab.
- Scroll to the **Host Users and Groups** area.

The **UNIX** section displays a summary of the number of users in each group associated with the selected storage VM.

- Click  in the **UNIX** section.
- Click the **Groups** tab to view details about that group.
- To view the users in a group, select the group, then click the **Users** tab.

## Add, edit, or delete a UNIX group

In System Manager, you can manage UNIX groups by adding, editing, or deleting them.

### Steps

- In System Manager, view the list of UNIX groups. Refer to [View UNIX users and groups](#).
- On the **Groups** tab, you can manage groups with the following tasks:

| To perform this action... | Perform these steps... |
|---------------------------|------------------------|
|---------------------------|------------------------|

|                |                                                                                                                                                                                                             |
|----------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Add a group    | 1. Click  <b>Add</b> .<br>2. Enter the group information.<br>3. (Optional) Specify associated users.                       |
| Edit a group   | 1. Select the group.<br>2. Click  <b>Edit</b> .<br>3. Modify the group information.<br>4. (Optional) Add or remove users. |
| Delete a group | 1. Select the group or groups you want to delete.<br>2. Click  <b>Delete</b> .                                            |

## Manage UNIX Users

In System Manager, you can manage Windows users by adding, editing, or deleting them.

### Steps

1. In System Manager, view the list of users for the group. Refer to [View UNIX users and groups](#).
2. On the **Users** tab, you can manage users with the following tasks:

| To perform this action... | Perform these steps...                                                                                                                                                                 |
|---------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Add a user                | 1. Click  <b>Add</b> .<br>2. Enter the user information.                                            |
| Edit a user               | 1. Select the user you want to edit.<br>2. Click  <b>Edit</b> .<br>3. Modify the user information. |
| Delete a user             | 1. Select the user or users you want to delete.<br>2. Click  <b>Delete</b> .                       |

## Monitor NFS active clients

Beginning with ONTAP 9.8, System Manager shows which NFS client connections are active when NFS is licensed on a cluster.

This allows you to quickly verify which NFS clients are actively connect to a storage VM, which are connected but idle, and which are disconnected.

For each NFS client IP address, the **NFS Clients** display shows:

- \* Time of last access
- \* Network interface IP address
- \* NFS connection version

\* Storage VM name

In addition, a list of NFS clients active in the last 48 hours is also shown in the **Storage>Volumes** display and a count of NFS clients is included in the **Dashboard** display.

### Step

1. Display NFS client activity: Click **Hosts > NFS Clients**.

## Enable NAS storage

### Enable NAS storage for Linux servers using NFS

Create or modify storage VMs to enable NFS servers for serving data to Linux clients.

This procedure enables a new or existing storage VM for the NFS protocol. It is assumed that configuration details are available for any networking, authentication, or security services required in your environment.

### Steps

1. Enable NFS on a storage VM.
  - a. For new storage VMs: click **Storage > Storage VMs**, click **Add**, enter a storage VM name, and in the **SMB/CIFS, NFS, S3** tab, select **Enable NFS**.
    - Confirm the default language.
    - Add network interfaces.
    - Update storage VM administrator account information (optional).
  - b. For existing storage VMs: click **Storage > Storage VMs**, select a storage VM, click **Settings**, and then click under **NFS**.
2. Open the export policy of the storage VM root volume:
  - a. Click **Storage > Volumes**, select the root volume of the storage VM (which by default is *volume-name\_root*), and then click on the policy that is displayed under **Export Policy**.
  - b. Click **Add** to add a rule.
    - Client specification = *0.0.0.0/0*
    - Access protocols = NFS
    - Access details = UNIX Read-Only
3. Configure DNS for host-name resolution: click **Storage > Storage VMs**, select the storage VM, click **Settings**, and then click under **DNS**.
4. Configure name services as required.
  - a. Click **Storage > Storage VMs**, select the storage VM, click **Settings**, and then click for LDAP or NIS.
  - b. Include any changes in the name services switch file: click in the Name Services Switch tile.

5. Configure Kerberos if required:

- Click **Storage > Storage VMs**, select the storage VM, and then click **Settings**.
- Click → in the Kerberos tile and then click **Add**.

### Enable NAS storage for Windows servers using SMB

Create or modify storage VMs to enable SMB servers for serving data to Windows clients.

This procedure enables a new or existing storage VM for the SMB protocol. It is assumed that configuration details are available for any networking, authentication, or security services required in your environment.

#### Steps

1. Enable SMB on a storage VM.
  - a. For new storage VMs: click **Storage > Storage VMs**, click **Add**, enter a storage VM name, and in the **SMB/CIFS, NFS, S3** tab, select **Enable SMB/CIFS**.
    - Enter the following information:
      - Administrator name and password
      - Server name
      - Active directory domain
    - Confirm the Organizational Unit.
    - Confirm the DNS values.
    - Confirm the default language.
    - Add network interfaces.
    - Update storage VM administrator account information (optional).
  - b. For existing storage VMs:: click **Storage > Storage VMs**, select a storage VM, click **Settings**, and then click under **SMB**.
2. Open the export policy of the storage VM root volume:
  - a. Click **Storage > Volumes**, select the root volume of the storage VM (which by default is *volume-name\_root*), and then click on the policy that is displayed under **Export Policy**.
  - b. Click **Add** to add a rule.
    - Client specification = 0.0.0.0/0
    - Access protocols = SMB
    - Access details = NTFS Read-Only
3. Configure DNS for host-name resolution:
  - a. Click **Storage > Storage VMs**, select the storage VM, click **Settings**, and then click under **DNS**.
  - b. Switch to the DNS server and map the SMB server.

- Create forward (A - Address record) and reverse (PTR - Pointer record) lookup entries to map the SMB server name to the IP address of the data network interface.
- If you use NetBIOS aliases, create an alias canonical name (CNAME resource record) lookup entry to map each alias to the IP address of the SMB server's data network interface.

4. Configure name services as required

- a. Click **Storage > Storage VMs**, select the storage VM, click **Settings**, and then click under **LDAP or NIS**.
- b. Include any changes in the name services switch file: click under **Name Services Switch**.

5. Configure Kerberos if required:

- a. Click **Storage > Storage VMs**, select the storage VM, and then click **Settings**.
- b. Click under **Kerberos** and then click **Add**.

### Enable NAS storage for both Windows and Linux using both NFS and SMB

Create or modify storage VMs to enable NFS and SMB servers to serve data to Linux and Windows clients.

This procedure enables a new or existing storage VM to serve both NFS and SMB protocols. It is assumed that configuration details are available for any networking, authentication, or security services required in your environment.

### Steps

1. Enable NFS and SMB on a storage VM.
  - a. For new storage VMs: click **Storage > Storage VMs**, click **Add**, enter a storage VM name, and in the **SMB/CIFS, NFS, S3** tab, select **Enable SMB/CIFS** and **Enable NFS**.
    - Enter the following information:
      - Administrator name and password
      - Server name
      - Active directory domain
    - Confirm the Organizational Unit.
    - Confirm the DNS values.
    - Confirm the default language.
    - Add network interfaces.
    - Update storage VM administrator account information (optional).
  - b. For existing storage VMs: click **Storage > Storage VMs**, select a storage VM, and then click **Settings**. Complete the following sub-steps if NFS or SMB is not already enabled.
    - Click under **NFS**.
    - Click under **SMB**.

2. Open the export policy of the storage VM root volume:
  - a. Click **Storage > Volumes**, select the root volume of the storage VM (which by default is *volume-name\_root*), and then click on the policy that is displayed under **Export Policy**.
  - b. Click **Add** to add a rule.
    - Client specification = 0.0.0.0/0
    - Access protocols = NFS
    - Access details = NFS Read-Only
3. Configure DNS for host-name resolution:
  - a. Click **Storage > Storage VMs**, select the storage VM, click **Settings**, and then click  under **DNS**.
  - b. When DNS configuration is complete, switch to the DNS server and map the SMB server.
    - Create forward (A - Address record) and reverse (PTR - Pointer record) lookup entries to map the SMB server name to the IP address of the data network interface.
    - If you use NetBIOS aliases, create an alias canonical name (CNAME resource record) lookup entry to map each alias to the IP address of the SMB server's data network interface.
4. Configure name services as required:
  - a. Click **Storage > Storage VMs**, select the storage VM, click **Settings**, and then click  for LDAP or NIS.
  - b. Include any changes in the name services switch file: click  under **Name Services Switch**.
5. Configure Kerberos if required: click  in the Kerberos tile and then click **Add**.
6. Map UNIX and Windows user names if required: click  under **Name Mapping** and then click **Add**.

You should use this procedure only if your site has Windows and UNIX user accounts that do not map implicitly, which is when the lowercase version of each Windows user name matches the UNIX user name. This procedure can be done using LDAP, NIS, or local users. If you have two sets of users that do not match, you should configure name mapping.

## Configure NFS with the CLI

### NFS configuration overview with the CLI

You can use ONTAP 9 CLI commands to configure NFS client access to files contained in a new volume or qtree in a new or existing storage virtual machine (SVM).

Use these procedures if you want to configure access to a volume or qtree in the following way:

- You want to use any version of NFS currently supported by ONTAP: NFSv3, NFSv4, NFSv4.1, NFSv4.2, or NFSv4.1 with pNFS.
- You want to use the command-line interface (CLI), not System Manager or an automated scripting tool.

To use System Manager to configure NAS multiprotocol access, see [Provision NAS storage for both Windows and Linux using both NFS and SMB](#).

- You want to use best practices, not explore every available option.

Details about command syntax are available from CLI help and ONTAP man pages.

- UNIX file permissions will be used to secure the new volume.
- You have cluster administrator privileges, not SVM administrator privileges.

If you want details about the range of ONTAP NFS protocol capabilities, consult the [NFS reference overview](#).

## Other ways to do this in ONTAP

| To perform these tasks with...                                     | Refer to...                                                       |

## NFS configuration workflow

Configuring NFS involves assessing physical storage and networking requirements, and then choosing a workflow that is specific to your goal—configuring NFS access to a new or existing SVM, or adding a volume or qtree to an existing SVM that is already fully configured for NFS access.

## Preparation

### Assess physical storage requirements

Before provisioning NFS storage for clients, you must ensure that there is sufficient space in an existing aggregate for the new volume. If there is not, you can add disks to an existing aggregate or create a new aggregate of the desired type.

### Steps

1. Display available space in existing aggregates:

```
storage aggregate show
```

If there is an aggregate with sufficient space, record its name in the worksheet.

```

cluster::> storage aggregate show
Aggregate Size Available Used% State #Vols Nodes RAID Status
----- ----- ----- ----- ----- ----- ----- ----- -----
aggr_0 239.0GB 11.13GB 95% online 1 node1 raid_dp,
 normal
aggr_1 239.0GB 11.13GB 95% online 1 node1 raid_dp,
 normal
aggr_2 239.0GB 11.13GB 95% online 1 node2 raid_dp,
 normal
aggr_3 239.0GB 11.13GB 95% online 1 node2 raid_dp,
 normal
aggr_4 239.0GB 238.9GB 95% online 5 node3 raid_dp,
 normal
aggr_5 239.0GB 239.0GB 95% online 4 node4 raid_dp,
 normal
 6 entries were displayed.

```

2. If there are no aggregates with sufficient space, add disks to an existing aggregate by using the `storage aggregate add-disks` command, or create a new aggregate by using the `storage aggregate create` command.

## Related information

[ONTAP concepts](#)

## Assess networking requirements

Before providing NFS storage to clients, you must verify that networking is correctly configured to meet the NFS provisioning requirements.

### What you'll need

The following cluster networking objects must be configured:

- Physical and logical ports
- Broadcast domains
- Subnets (if required)
- IPspaces (as required, in addition to the default IPspace)
- Failover groups (as required, in addition to the default failover group for each broadcast domain)
- External firewalls

### Steps

1. Display the available physical and virtual ports:

```
network port show
```

- When possible, you should use the port with the highest speed for the data network.
- All components in the data network must have the same MTU setting for best performance.

2. If you are planning to use a subnet name to allocate the IP address and network mask value for a LIF, verify that the subnet exists and has sufficient addresses available: +

```
network subnet show
```

Subnets contain a pool of IP addresses that belong to the same layer 3 subnet. Subnets are created by using the `network subnet create` command.

3. Display available IPspaces:

```
network ipspace show
```

You can use the default IPspace or a custom IPspace.

4. If you want to use IPv6 addresses, verify that IPv6 is enabled on the cluster:

```
network options ipv6 show
```

If required, you can enable IPv6 by using the `network options ipv6 modify` command.

## Decide where to provision new NFS storage capacity

Before you create a new NFS volume or qtree, you must decide whether to place it in a new or existing SVM, and how much configuration the SVM requires. This decision determines your workflow.

### Choices

- If you want to provision a volume or qtree on a new SVM, or on an existing SVM that has NFS enabled but not configured, complete the steps in both "Configuring NFS access to an SVM" and "Adding NFS storage to an NFS-enabled SVM".

#### [Configure NFS access to an SVM](#)

#### [Add NFS storage to an NFS-enabled SVM](#)

You might choose to create a new SVM if one of the following is true:

- You are enabling NFS on a cluster for the first time.
- You have existing SVMs in a cluster in which you do not want to enable NFS support.
- You have one or more NFS-enabled SVMs in a cluster, and you want another NFS server in an isolated namespace (multi-tenancy scenario).

You should also choose this option to provision storage on an existing SVM that has NFS enabled but not configured. This might be the case if you created the SVM for SAN access or if no protocols were enabled when the SVM was created.

After enabling NFS on the SVM, proceed to provision a volume or qtree.

- If you want to provision a volume or qtree on an existing SVM that is fully configured for NFS access, complete the steps in "Adding NFS storage to an NFS-enabled SVM".

#### [Adding NFS storage to an NFS-enabled SVM](#)

## Worksheet for gathering NFS configuration information

The NFS configuration worksheet enables you to collect the required information to set up NFS access for clients.

You should complete one or both sections of the worksheet depending on the decision you made about where to provision storage:

If you are configuring NFS access to an SVM, you should complete both sections.

- Configuring NFS access to an SVM
- Adding storage capacity to an NFS-enabled SVM

If you are adding storage capacity to an NFS-enabled SVM, you should complete only:

- Adding storage capacity to an NFS-enabled SVM

See the command man pages for details about the parameters.

### Configure NFS access to an SVM

#### Parameters for creating an SVM

You supply these values with the `vserver create` command if you are creating a new SVM.

| Field                                   | Description                                                                                                                                                          | Your value |
|-----------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------|
| <code>-vserver</code>                   | A name you supply for the new SVM that is either a fully qualified domain name (FQDN) or follows another convention that enforces unique SVM names across a cluster. |            |
| <code>-aggregate</code>                 | The name of an aggregate in the cluster with sufficient space for new NFS storage capacity.                                                                          |            |
| <code>-rootvolume</code>                | A unique name you supply for the SVM root volume.                                                                                                                    |            |
| <code>-rootvolume-security-style</code> | Use the UNIX security style for the SVM.                                                                                                                             | unix       |
| <code>-language</code>                  | Use the default language setting in this workflow.                                                                                                                   | C.UTF-8    |
| <code>ipspace</code>                    | IPspaces are distinct IP address spaces in which (storage virtual machines (SVMs)) reside.                                                                           |            |

## Parameters for creating an NFS server

You supply these values with the `vserver nfs create` command when you create a new NFS server and specify supported NFS versions.

If you are enabling NFSv4 or later, you should use LDAP for improved security.

| Field                                      | Description                                                                                                                                                                                 | Your value |
|--------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------|
| <code>-v3, -v4.0, -v4.1, -v4.1-pnfs</code> | Enable NFS versions as needed.<br><br> v4.2 is also supported in ONTAP 9.8 and later when v4.1 is enabled. |            |
| <code>-v4-id-domain</code>                 | ID mapping domain name.                                                                                                                                                                     |            |
| <code>-v4-numeric-ids</code>               | Support for numeric owner IDs (enabled or disabled).                                                                                                                                        |            |

## Parameters for creating a LIF

You supply these values with the `network interface create` command when you are creating LIFs.

If you are using Kerberos, you should enable Kerberos on multiple LIFs.

| Field                       | Description                                                                                                                    | Your value |
|-----------------------------|--------------------------------------------------------------------------------------------------------------------------------|------------|
| <code>-lif</code>           | A name you supply for the new LIF.                                                                                             |            |
| <code>-role</code>          | Use the data LIF role in this workflow.                                                                                        | data       |
| <code>-data-protocol</code> | Use only the NFS protocol in this workflow.                                                                                    | nfs        |
| <code>-home-node</code>     | The node to which the LIF returns when the <code>network interface revert</code> command is run on the LIF.                    |            |
| <code>-home-port</code>     | The port or interface group to which the LIF returns when the <code>network interface revert</code> command is run on the LIF. |            |

|                  |                                                                                                               |      |
|------------------|---------------------------------------------------------------------------------------------------------------|------|
| -address         | The IPv4 or IPv6 address on the cluster that will be used for data access by the new LIF.                     |      |
| -netmask         | The network mask and gateway for the LIF.                                                                     |      |
| -subnet          | A pool of IP addresses. Used instead of -address and -netmask to assign addresses and netmasks automatically. |      |
| -firewall-policy | Use the default data firewall policy in this workflow.                                                        | data |

### Parameters for DNS host name resolution

You supply these values with the `vserver services name-service dns create` command when you are configuring DNS.

| Field         | Description                                        | Your value |
|---------------|----------------------------------------------------|------------|
| -domains      | Up to five DNS domain names.                       |            |
| -name-servers | Up to three IP addresses for each DNS name server. |            |

### Name service information

### Parameters for creating local users

You supply these values if you are creating local users by using the `vserver services name-service unix-user create` command. If you are configuring local users by loading a file containing UNIX users from a uniform resource identifier (URI), you do not need to specify these values manually.

|         | User name (-user) | User ID (-id) | Group ID (-primary-gid) | Full name (-full-name) |
|---------|-------------------|---------------|-------------------------|------------------------|
| Example | johnm             | 123           | 100                     | John Miller            |
| 1       |                   |               |                         |                        |
| 2       |                   |               |                         |                        |
| 3       |                   |               |                         |                        |
| ...     |                   |               |                         |                        |

|   |  |  |  |  |
|---|--|--|--|--|
| n |  |  |  |  |
|---|--|--|--|--|

## Parameters for creating local groups

You supply these values if you are creating local groups by using the `vserver services name-service unix-group create` command. If you are configuring local groups by loading a file containing UNIX groups from a URI, you do not need to specify these values manually.

|         | <b>Group name (-name)</b> | <b>Group ID (-id)</b> |
|---------|---------------------------|-----------------------|
| Example | Engineering               | 100                   |
| 1       |                           |                       |
| 2       |                           |                       |
| 3       |                           |                       |
| ...     |                           |                       |
| n       |                           |                       |

## Parameters for NIS

You supply these values with the `vserver services name-service nis-domain create` command.

Beginning with ONTAP 9.2, the field `-nis-servers` replaces the field `-servers`. This new field can take either a hostname or an IP address for the NIS server.

| <b>Field</b>              | <b>Description</b>                                                                                                    | <b>Your value</b>                       |
|---------------------------|-----------------------------------------------------------------------------------------------------------------------|-----------------------------------------|
| <code>-domain</code>      | The NIS domain that the SVM will use for name lookups.                                                                |                                         |
| <code>-active</code>      | The active NIS domain server.                                                                                         | <code>true</code> or <code>false</code> |
| <code>-servers</code>     | ONTAP 9.0, 9.1: One or more IP addresses of NIS servers used by the NIS domain configuration.                         |                                         |
| <code>-nis-servers</code> | ONTAP 9.2: A comma-separated list of IP addresses and hostnames for the NIS servers used by the domain configuration. |                                         |

## Parameters for LDAP

You supply these values with the `vserver services name-service ldap client create` command.

You will also need a self-signed root CA certificate `.pem` file.

Beginning with ONTAP 9.2, the field `-ldap-servers` replaces the field `-servers`. This new field can take either a hostname or an IP address for the LDAP server.

| Field                              | Description                                                                                                                                           | Your value |
|------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------|------------|
| <code>-vserver</code>              | The name of the SVM for which you want to create an LDAP client configuration.                                                                        |            |
| <code>-client-config</code>        | The name you assign for the new LDAP client configuration.                                                                                            |            |
| <code>-servers</code>              | ONTAP 9.0, 9.1: One or more LDAP servers by IP address in a comma-separated list.                                                                     |            |
| <code>-ldap-servers</code>         | ONTAP 9.2: A comma-separated list of IP addresses and hostnames for the LDAP servers.                                                                 |            |
| <code>-query-timeout</code>        | Use the default 3 seconds for this workflow.                                                                                                          | 3          |
| <code>-min-bind-level</code>       | The minimum bind authentication level. The default is <code>anonymous</code> . Must be set to <code>sasl</code> if signing and sealing is configured. |            |
| <code>-preferred-ad-servers</code> | One or more preferred Active Directory servers by IP address in a comma-delimited list.                                                               |            |
| <code>-ad-domain</code>            | The Active Directory domain.                                                                                                                          |            |
| <code>-schema</code>               | The schema template to use. You can use a default or custom schema.                                                                                   |            |
| <code>-port</code>                 | Use the default LDAP server port 389 for this workflow.                                                                                               | 389        |
| <code>-bind-dn</code>              | The Bind user distinguished name.                                                                                                                     |            |

| Field             | Description                                                       | Your value |
|-------------------|-------------------------------------------------------------------|------------|
| -base-dn          | The base distinguished name. The default is "" (root).            |            |
| -base-scope       | Use the default base search scope subnet for this workflow.       | subnet     |
| -session-security | Enables LDAP signing or signing and sealing. The default is none. |            |
| -use-start-tls    | Enables LDAP over TLS. The default is false.                      |            |

### Parameters for Kerberos authentication

You supply these values with the `vserver nfs kerberos realm create` command. Some of the values will differ depending on whether you use Microsoft Active Directory as a Key Distribution Center (KDC) server, or MIT or other UNIX KDC server.

| Field             | Description                                       | Your value |
|-------------------|---------------------------------------------------|------------|
| -vserver          | The SVM that will communicate with the KDC.       |            |
| -realm            | The Kerberos realm.                               |            |
| -clock-skew       | Permitted clock skew between clients and servers. |            |
| -kdc-ip           | KDC IP address.                                   |            |
| -kdc-port         | KDC port number.                                  |            |
| -adserver-name    | Microsoft KDC only: AD server name.               |            |
| -adserver-ip      | Microsoft KDC only: AD server IP address.         |            |
| -adminserver-ip   | UNIX KDC only: Admin server IP address.           |            |
| -adminserver-port | UNIX KDC only: Admin server port number.          |            |

|                                   |                                            |                       |
|-----------------------------------|--------------------------------------------|-----------------------|
| <code>-passwordserver-ip</code>   | UNIX KDC only: Password server IP address. |                       |
| <code>-passwordserver-port</code> | UNIX KDC only: Password server port.       |                       |
| <code>-kdc-vendor</code>          | KDC vendor.                                | { Microsoft   Other } |
| <code>-comment</code>             | Any desired comments.                      |                       |

You supply these values with the `vserver nfs kerberos interface enable` command.

| Field                             | Description                                                                                                                                                      | Your value |
|-----------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------|
| <code>-vserver</code>             | The name of the SVM for which you want to create a Kerberos configuration.                                                                                       |            |
| <code>-lif</code>                 | The data LIF on which you will enable Kerberos. You can enable Kerberos on multiple LIFs.                                                                        |            |
| <code>-spn</code>                 | The Service Principle Name (SPN)                                                                                                                                 |            |
| <code>-permitted-enc-types</code> | The permitted encryption types for Kerberos over NFS; <code>aes-256</code> is recommended, depending on client capabilities.                                     |            |
| <code>-admin-username</code>      | The KDC administrator credentials to retrieve the SPN secret key directly from the KDC. A password is required                                                   |            |
| <code>-keytab-uri</code>          | The keytab file from the KDC containing the SPN key if you do not have KDC administrator credentials.                                                            |            |
| <code>-ou</code>                  | The organizational unit (OU) under which the Microsoft Active Directory server account will be created when you enable Kerberos using a realm for Microsoft KDC. |            |

#### Adding storage capacity to an NFS-enabled SVM

#### Parameters for creating export policies and rules

You supply these values with the `vserver export-policy create` command.

| Field                    | Description                                        | Your value |
|--------------------------|----------------------------------------------------|------------|
| <code>-vserver</code>    | The name of the SVM that will host the new volume. |            |
| <code>-policyname</code> | A name you supply for a new export policy.         |            |

You supply these values for each rule with the `vserver export-policy rule create` command.

| Field                     | Description                                   | Your value       |
|---------------------------|-----------------------------------------------|------------------|
| <code>-clientmatch</code> | Client match specification.                   |                  |
| <code>-ruleindex</code>   | Position of export rule in the list of rules. |                  |
| <code>-protocol</code>    | Use NFS in this workflow.                     | <code>nfs</code> |
| <code>-rorule</code>      | Authentication method for read-only access.   |                  |
| <code>-rwrule</code>      | Authentication method for read-write access.  |                  |
| <code>-superuser</code>   | Authentication method for superuser access.   |                  |
| <code>-anon</code>        | User ID to which anonymous users are mapped.  |                  |

You must create one or more rules for each export policy.

## Parameters for creating a volume

You supply these values with the `volume create` command if you are creating a volume instead of a qtree.

| Field                         | Description                                                                                              | Your value |
|-------------------------------|----------------------------------------------------------------------------------------------------------|------------|
| <code>-vserver</code>         | The name of a new or existing SVM that will host the new volume.                                         |            |
| <code>-volume</code>          | A unique descriptive name you supply for the new volume.                                                 |            |
| <code>-aggregate</code>       | The name of an aggregate in the cluster with sufficient space for the new NFS volume.                    |            |
| <code>-size</code>            | An integer you supply for the size of the new volume.                                                    |            |
| <code>-user</code>            | Name or ID of the user that is set as the owner of the volume's root.                                    |            |
| <code>-group</code>           | Name or ID of the group that is set as the owner of the volume's root.                                   |            |
| <code>--security-style</code> | Use the UNIX security style for this workflow.                                                           | unix       |
| <code>-junction-path</code>   | Location under root (/) where the new volume is to be mounted.                                           |            |
| <code>-export-policy</code>   | If you are planning to use an existing export policy, you can enter its name when you create the volume. |            |

## Parameters for creating a qtree

You supply these values with the `volume qtree create` command if you are creating a qtree instead of a volume.

| Field                 | Description                                                           | Your value |
|-----------------------|-----------------------------------------------------------------------|------------|
| <code>-vserver</code> | The name of the SVM on which the volume containing the qtree resides. |            |

|                   |                                                                                                                                                                  |  |
|-------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------|--|
| -volume           | The name of the volume that will contain the new qtree.                                                                                                          |  |
| -qtree            | A unique descriptive name you supply for the new qtree, 64 characters or less.                                                                                   |  |
| -qtree-path       | The qtree path argument in the format<br><code>/vol/volume_name/qtree_name</code> can be specified instead of specifying volume and qtree as separate arguments. |  |
| -unix-permissions | Optional: The UNIX permissions for the qtree.                                                                                                                    |  |
| -export-policy    | If you are planning to use an existing export policy, you can enter its name when you create the qtree.                                                          |  |

## Configure NFS access to an SVM

### Create an SVM

If you do not already have at least one SVM in a cluster to provide data access to NFS clients, you must create one.

### Before you begin

- Beginning in ONTAP 9.13.1, you can set a maximum capacity for a storage VM. You can also configure alerts when the SVM approaches a threshold capacity level. For more information, see [Manage SVM capacity](#).

### Steps

#### 1. Create an SVM:

```
vserver create -vserver vserver_name -rootvolume root_volume_name -aggregate aggregate_name -rootvolume-security-style unix -language C.UTF-8 -ipspace ipspace_name
```

- Use the UNIX setting for the `-rootvolume-security-style` option.
- Use the default C.UTF-8 `-language` option.
- The `ipspace` setting is optional.

#### 2. Verify the configuration and status of the newly created SVM:

```
vserver show -vserver vserver_name
```

The Allowed Protocols field must include NFS. You can edit this list later.

The Vserver Operational State field must display the running state. If it displays the initializing state, it means that some intermediate operation such as root volume creation failed, and you must delete the SVM and re-create it.

## Examples

The following command creates an SVM for data access in the IPspace ipspaceA:

```
cluster1::> vserver create -vserver vs1.example.com -rootvolume root_vs1
-aggregate aggr1
-rootvolume-security-style unix -language C.UTF-8 -ipspace ipspaceA

[Job 2059] Job succeeded:
Vserver creation completed
```

The following command shows that an SVM was created with a root volume of 1 GB, and it was started automatically and is in running state. The root volume has a default export policy that does not include any rules, so the root volume is not exported upon creation.

```
cluster1::> vserver show -vserver vs1.example.com
 Vserver: vs1.example.com
 Vserver Type: data
 Vserver Subtype: default
 Vserver UUID: b8375669-19b0-11e5-b9d1-
00a0983d9736
 Root Volume: root_vs1
 Aggregate: aggr1
 NIS Domain: -
 Root Volume Security Style: unix
 LDAP Client: -
 Default Volume Language Code: C.UTF-8
 Snapshot Policy: default
 Comment:
 Quota Policy: default
 List of Aggregates Assigned: -
Limit on Maximum Number of Volumes allowed: unlimited
 Vserver Admin State: running
 Vserver Operational State: running
 Vserver Operational State Stopped Reason: -
 Allowed Protocols: nfs, cifs, fcp, iscsi, ndmp
 Disallowed Protocols: -
 QoS Policy Group: -
 Config Lock: false
 IPspace Name: ipspaceA
```

Beginning in ONTAP 9.13.1, you can set an adaptive QoS policy group template, applying a throughput floor and ceiling limit to volumes in the SVM. You can only apply this policy after you create the SVM. To learn more about this process, see [Set an adaptive policy group template](#).

## Verify that the NFS protocol is enabled on the SVM

Before you can configure and use NFS on SVMs, you must verify that the protocol is enabled.

### About this task

This is typically done during SVM setup, but if you did not enable the protocol during setup, you can enable it later by using the `vserver add-protocols` command.

You cannot add or remove a protocol from a LIF once it is created.

You can also disable protocols on SVMs using the `vserver remove-protocols` command.

### Steps

1. Check which protocols are currently enabled and disabled for the SVM:

```
vserver show -vserver vserver_name -protocols
```

You can also use the `vserver show-protocols` command to view the currently enabled protocols on all SVMs in the cluster.

2. If necessary, enable or disable a protocol:

- To enable the NFS protocol:

```
vserver add-protocols -vserver vserver_name -protocols nfs
```

- To disable a protocol:

```
vserver remove-protocols -vserver vserver_name -protocols protocol_name
[,protocol_name,...]
```

3. Confirm that the enabled and disabled protocols were updated correctly:

```
vserver show -vserver vserver_name -protocols
```

### Example

The following command displays which protocols are currently enabled and disabled (allowed and disallowed) on the SVM named vs1:

```
vs1::> vserver show -vserver vs1.example.com -protocols
Vserver Allowed Protocols Disallowed Protocols
----- -----
vs1.example.com nfs cifs, fcp, iscsi, ndmp
```

The following command allows access over NFS by adding `nfs` to the list of enabled protocols on the SVM

named vs1:

```
vs1::> vserver add-protocols -vserver vs1.example.com -protocols nfs
```

### Open the export policy of the SVM root volume

The default export policy of the SVM root volume must include a rule to allow all clients open access through NFS. Without such a rule, all NFS clients are denied access to the SVM and its volumes.

#### About this task

When a new SVM is created, a default export policy (called default) is created automatically for the root volume of the SVM. You must create one or more rules for the default export policy before clients can access data on the SVM.

You should verify that access is open to all NFS clients in the default export policy, and later restrict access to individual volumes by creating custom export policies for individual volumes or qtrees.

#### Steps

1. If you are using an existing SVM, check the default root volume export policy:

```
vserver export-policy rule show
```

The command output should be similar to the following:

```
cluster::> vserver export-policy rule show -vserver vs1.example.com
-policyname default -instance

Vserver: vs1.example.com
Policy Name: default
Rule Index: 1
Access Protocol: nfs
Client Match Hostname, IP Address, Netgroup, or Domain: 0.0.0.0/0
 RO Access Rule: any
 RW Access Rule: any
User ID To Which Anonymous Users Are Mapped: 65534
 Superuser Security Types: any
 Honor SetUID Bits in SETATTR: true
 Allow Creation of Devices: true
```

If such a rule exists that allows open access, this task is complete. If not, proceed to the next step.

2. Create an export rule for the SVM root volume:

```
vserver export-policy rule create -vserver vserver_name -policyname default
-ruleindex 1 -protocol nfs -clientmatch 0.0.0.0/0 -rorule any -rwrule any
-superuser any
```

If the SVM will only contain volumes secured by Kerberos, you can set the export rule options `-rorule`, `-rwrule`, and `-superuser` for the root volume to `krb5` or `krb5i`. For example:

```
-rorule krb5i -rwrule krb5i -superuser krb5i
```

3. Verify rule creation by using the `vserver export-policy rule show` command.

## Result

Any NFS client can now access any volume or qtree created on the SVM.

## Create an NFS server

After verifying that NFS is licensed on your cluster, you can use the `vserver nfs create` command to create an NFS server on the SVM and specify the NFS versions it supports.

### What you'll need

The SVM must have been configured to allow the NFS protocol.

### About this task

The SVM can be configured to support one or more versions of NFS. If you are supporting NFSv4 or later:

- The NFSv4 user ID mapping domain name must be the same on the NFSv4 server and target clients.

It does not necessarily need to be the same as an LDAP or NIS domain name as long as the NFSv4 server and clients are using the same name.

- Target clients must support the NFSv4 numeric ID setting.
- For security reasons, you should use LDAP for name services in NFSv4 deployments.

## Steps

1. Verify that NFS is licensed on your cluster:

```
system license show -package nfs
```

If it is not, contact your sales representative.

2. Create an NFS server:

```
vserver nfs create -vserver vserver_name -v3 {enabled|disabled} -v4.0
{enabled|disabled} -v4-id-domain nfv4_id_domain -v4-numeric-ids
{enabled|disabled} -v4.1 {enabled|disabled} -v4.1-pnfs {enabled|disabled}
```

You can choose to enable any combination of NFS versions. If you want to support pNFS, you must enable both `-v4.1` and `-v4.1-pnfs` options.

If you enable v4 or later, you should also be sure that the following options are set correctly:

- `-v4-id-domain`

This optional parameter specifies the domain portion of the string form of user and group names as defined by the NFSv4 protocol. By default, ONTAP uses the NIS domain if one is set; if not, the DNS

domain is used. You must supply a value that matches the domain name used by target clients.

- -v4-numeric-ids

This optional parameter specifies whether the support for numeric string identifiers in NFSv4 owner attributes is enabled. The default setting is enabled but you should verify that the target clients support it.

You can enable additional NFS features later by using the vserver nfs modify command.

### 3. Verify that NFS is running:

```
vserver nfs status -vserver vserver_name
```

### 4. Verify that NFS is configured as desired:

```
vserver nfs show -vserver vserver_name
```

## Examples

The following command creates an NFS server on the SVM named vs1 with NFSv3 and NFSv4.0 enabled:

```
vs1::> vserver nfs create -vserver vs1 -v3 enabled -v4.0 enabled -v4-id
-domain my_domain.com
```

The following commands verify the status and configuration values of the new NFS server named vs1:

```
vs1::> vserver nfs status -vserver vs1
The NFS server is running on Vserver "vs1".

vs1::> vserver nfs show -vserver vs1

 Vserver: vs1
 General NFS Access: true
 NFS v3: enabled
 NFS v4.0: enabled
 UDP Protocol: enabled
 TCP Protocol: enabled
 Default Windows User: -
 NFSv4.0 ACL Support: disabled
 NFSv4.0 Read Delegation Support: disabled
 NFSv4.0 Write Delegation Support: disabled
 NFSv4 ID Mapping Domain: my_domain.com
...
```

## Create a LIF

A LIF is an IP address associated with a physical or logical port. If there is a component

failure, a LIF can fail over to or be migrated to a different physical port, thereby continuing to communicate with the network.

### What you'll need

- The underlying physical or logical network port must have been configured to the administrative `up` status.
- If you are planning to use a subnet name to allocate the IP address and network mask value for a LIF, the subnet must already exist.

Subnets contain a pool of IP addresses that belong to the same layer 3 subnet. They are created using the `network subnet create` command.

- The mechanism for specifying the type of traffic handled by a LIF has changed. For ONTAP 9.5 and earlier, LIFs used roles to specify the type of traffic it would handle. Beginning with ONTAP 9.6, LIFs use service policies to specify the type of traffic it would handle.

### About this task

- You can create both IPv4 and IPv6 LIFs on the same network port.
- If you are using Kerberos authentication, enable Kerberos on multiple LIFs.
- If you have a large number of LIFs in your cluster, you can verify the LIF capacity supported on the cluster by using the `network interface capacity show` command and the LIF capacity supported on each node by using the `network interface capacity details show` command (at the advanced privilege level).
- Beginning with ONTAP 9.7, if other LIFs already exist for the SVM in the same subnet, you do not need to specify the home port of the LIF. ONTAP automatically chooses a random port on the specified home node in the same broadcast domain as the other LIFs already configured in the same subnet.

Beginning with ONTAP 9.4, FC-NVMe is supported. If you are creating an FC-NVMe LIF you should be aware of the following:

- The NVMe protocol must be supported by the FC adapter on which the LIF is created.
- FC-NVMe can be the only data protocol on data LIFs.
- One LIF handling management traffic must be configured for every storage virtual machine (SVM) supporting SAN.
- NVMe LIFs and namespaces must be hosted on the same node.
- Only one NVMe LIF handling data traffic can be configured per SVM

### Steps

#### 1. Create a LIF:

```
network interface create -vserver vserver_name -lif lif_name -role data -data
-protocol nfs -home-node node_name -home-port port_name {-address IP_address
-netmask IP_address | -subnet-name subnet_name} -firewall-policy data -auto
-revert {true|false}
```

| Option | Description |
|--------|-------------|
|--------|-------------|

|                              |                                                                                                                                                                                                                                                                        |
|------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>ONTAP 9.5 and earlier</b> | <pre>network interface create -vserver vserver_name -lif lif_name -role data -data-protocol nfs -home-node node_name -home-port port_name {- address IP_address -netmask IP_address   -subnet-name subnet_name} -firewall -policy data -auto-revert {true false}</pre> |
| <b>ONTAP 9.6 and later</b>   | <pre>network interface create -vserver vserver_name -lif lif_name -role data -data-protocol nfs -home-node node_name -home-port port_name {- address IP_address -netmask IP_address   -subnet-name subnet_name} -firewall -policy data -auto-revert {true false}</pre> |

- The `-role` parameter is not required when creating a LIF using a service policy (beginning with ONTAP 9.6).
- The `-data-protocol` parameter must be specified when the LIF is created, and cannot be modified later without destroying and re-creating the data LIF.

The `-data-protocol` parameter is not required when creating a LIF using a service policy (beginning with ONTAP 9.6).

- `-home-node` is the node to which the LIF returns when the `network interface revert` command is run on the LIF.

You can also specify whether the LIF should automatically revert to the home-node and home-port with the `-auto-revert` option.

- `-home-port` is the physical or logical port to which the LIF returns when the `network interface revert` command is run on the LIF.
- You can specify an IP address with the `-address` and `-netmask` options, or you enable allocation from a subnet with the `-subnet_name` option.
- When using a subnet to supply the IP address and network mask, if the subnet was defined with a gateway, a default route to that gateway is added automatically to the SVM when a LIF is created using that subnet.
- If you assign IP addresses manually (without using a subnet), you might need to configure a default route to a gateway if there are clients or domain controllers on a different IP subnet. The `network route create` man page contains information about creating a static route within an SVM.
- For the `-firewall-policy` option, use the same default data as the LIF role.

You can create and add a custom firewall policy later if desired.

Beginning with ONTAP 9.10.1, firewall policies are deprecated and wholly replaced with LIF service policies. For more information, see [Configure firewall policies for LIFs](#).

- `-auto-revert` allows you to specify whether a data LIF is automatically reverted to its home node

under circumstances such as startup, changes to the status of the management database, or when the network connection is made. The default setting is `false`, but you can set it to `false` depending on network management policies in your environment.

2. Verify that the LIF was created successfully by using the `network interface show` command.
3. Verify that the configured IP address is reachable:

| To verify an... | Use...                     |
|-----------------|----------------------------|
| IPv4 address    | <code>network ping</code>  |
| IPv6 address    | <code>network ping6</code> |

4. If you are using Kerberos, repeat Steps 1 through 3 to create additional LIFs.

Kerberos must be enabled separately on each of these LIFs.

### Examples

The following command creates a LIF and specifies the IP address and network mask values using the `-address` and `-netmask` parameters:

```
network interface create -vserver vs1.example.com -lif datalif1 -role data
-data-protocol nfs -home-node node-4 -home-port elc -address 192.0.2.145
-netmask 255.255.255.0 -firewall-policy data -auto-revert true
```

The following command creates a LIF and assigns IP address and network mask values from the specified subnet (named `client1_sub`):

```
network interface create -vserver vs3.example.com -lif datalif3 -role data
-data-protocol nfs -home-node node-3 -home-port elc -subnet-name
client1_sub -firewall-policy data -auto-revert true
```

The following command shows all the LIFs in cluster-1. Data LIFs `datalif1` and `datalif3` are configured with IPv4 addresses, and `datalif4` is configured with an IPv6 address:

```
network interface show
```

| Vserver                   | Logical Interface | Status Admin/Oper | Network Address/Mask | Current Node   | Current Is Port |     |
|---------------------------|-------------------|-------------------|----------------------|----------------|-----------------|-----|
| Home                      |                   |                   |                      |                |                 |     |
| ---                       |                   |                   |                      |                |                 |     |
| cluster-1                 | cluster_mgmt      | up/up             | 192.0.2.3/24         | node-1         | e1a             |     |
| true                      | clus1             | up/up             | 192.0.2.12/24        | node-1         | e0a             |     |
| true                      | clus2             | up/up             | 192.0.2.13/24        | node-1         | e0b             |     |
| true                      | mgmt1             | up/up             | 192.0.2.68/24        | node-1         | e1a             |     |
| node-2                    | clus1             | up/up             | 192.0.2.14/24        | node-2         | e0a             |     |
| true                      | clus2             | up/up             | 192.0.2.15/24        | node-2         | e0b             |     |
| true                      | mgmt1             | up/up             | 192.0.2.69/24        | node-2         | e1a             |     |
| vs1.example.com           | datalif1          | up/down           | 192.0.2.145/30       | node-1         | e1c             |     |
| true                      | vs3.example.com   | datalif3          | up/up                | 192.0.2.146/30 | node-2          | e0c |
| true                      | datalif4          | up/up             | 2001::2/64           | node-2         | e0c             |     |
| 5 entries were displayed. |                   |                   |                      |                |                 |     |

The following command shows how to create a NAS data LIF that is assigned with the default-data-files service policy:

```
network interface create -vserver vs1 -lif lif2 -home-node node2 -homeport e0d -service-policy default-data-files -subnet-name ipspace1
```

### Enable DNS for host-name resolution

You can use the vserver services name-service dns command to enable DNS on an SVM, and configure it to use DNS for host-name resolution. Host names are

resolved using external DNS servers.

### What you'll need

A site-wide DNS server must be available for host name lookups.

You should configure more than one DNS server to avoid a single-point-of-failure. The `vserver services name-service dns create` command issues a warning if you enter only one DNS server name.

### About this task

The *Network Management Guide* contains information about configuring dynamic DNS on the SVM.

### Steps

1. Enable DNS on the SVM:

```
vserver services name-service dns create -vserver vserver_name -domains
domain_name -name-servers ip_addresses -state enabled
```

The following command enables external DNS server servers on the SVM vs1:

```
vserver services name-service dns create -vserver vs1.example.com
-domains example.com -name-servers 192.0.2.201,192.0.2.202 -state
enabled
```

Beginning with ONTAP 9.2, the `vserver services name-service dns create` command performs an automatic configuration validation and reports an error message if ONTAP cannot contact the name server.

2. Display the DNS domain configurations by using the `vserver services name-service dns show` command.

The following command displays the DNS configurations for all SVMs in the cluster:

```
vserver services name-service dns show
```

| Vserver         | State   | Domains     | Name | Servers                     |
|-----------------|---------|-------------|------|-----------------------------|
| cluster1        | enabled | example.com |      | 192.0.2.201,<br>192.0.2.202 |
| vs1.example.com | enabled | example.com |      | 192.0.2.201,<br>192.0.2.202 |

The following command displays detailed DNS configuration information for SVM vs1:

```
vserver services name-service dns show -vserver vs1.example.com
 Vserver: vs1.example.com
 Domains: example.com
 Name Servers: 192.0.2.201, 192.0.2.202
 Enable/Disable DNS: enabled
 Timeout (secs): 2
 Maximum Attempts: 1
```

3. Validate the status of the name servers by using the `vserver services name-service dns check` command.

The `vserver services name-service dns check` command is available beginning with ONTAP 9.2.

```
vserver services name-service dns check -vserver vs1.example.com

Vserver Name Server Status Status Details
----- ----- -----
----- -----
vs1.example.com 10.0.0.50 up Response time (msec): 2
vs1.example.com 10.0.0.51 up Response time (msec): 2
```

## Configure name services

### Configure name services overview

Depending on the configuration of your storage system, ONTAP needs to be able to look up host, user, group, or netgroup information to provide proper access to clients. You must configure name services to enable ONTAP to access local or external name services to obtain this information.

You should use a name service such as NIS or LDAP to facilitate name lookups during client authentication. It is best to use LDAP whenever possible for greater security, especially when deploying NFSv4 or later. You should also configure local users and groups in case external name servers are not available.

Name service information must be kept synchronized on all sources.

### Configure the name service switch table

You must configure the name service switch table correctly to enable ONTAP to consult local or external name services to retrieve host, user, group, netgroup, or name mapping information.

### What you'll need

You must have decided which name services you want to use for host, user, group, netgroup, or name mapping as applicable to your environment.

If you plan to use netgroups, all IPv6 addresses specified in netgroups must be shortened and compressed as specified in RFC 5952.

## About this task

Do not include information sources that are not being used. For example, if NIS is not being used in your environment, do not specify the `-sources nis` option.

## Steps

1. Add the necessary entries to the name service switch table:

```
vserver services name-service ns-switch create -vserver vserver_name -database database_name -sources source_names
```

2. Verify that the name service switch table contains the expected entries in the desired order:

```
vserver services name-service ns-switch show -vserver vserver_name
```

If you want to make any corrections, you must use the `vserver services name-service ns-switch modify` or `vserver services name-service ns-switch delete` commands.

## Example

The following example creates a new entry in the name service switch table for the SVM vs1 to use the local netgroup file and an external NIS server to look up netgroup information in that order:

```
cluster::> vserver services name-service ns-switch create -vserver vs1
-database netgroup -sources files,nis
```

## After you finish

- You must configure the name services you have specified for the SVM to provide data access.
- If you delete any name service for the SVM, you must remove it from the name service switch table as well.

The client access to the storage system might not work as expected, if you fail to delete the name service from the name service switch table.

## Configure local UNIX users and groups

### Configure local UNIX users and groups overview

You can use local UNIX users and groups on the SVM for authentication and name mappings. You can create UNIX users and groups manually, or you can load a file containing UNIX users or groups from a uniform resource identifier (URI).

There is a default maximum limit of 32,768 local UNIX user groups and group members combined in the cluster. The cluster administrator can modify this limit.

### Create a local UNIX user

You can use the `vserver services name-service unix-user create` command to create local UNIX users. A local UNIX user is a UNIX user you create on the

SVM as a UNIX name services option to be used in the processing of name mappings.

## Step

1. Create a local UNIX user:

```
vserver services name-service unix-user create -vserver vserver_name -user user_name -id integer -primary-gid integer -full-name full_name
```

*-user user\_name* specifies the user name. The length of the user name must be 64 characters or fewer.

*-id integer* specifies the user ID that you assign.

*-primary-gid integer* specifies the primary group ID. This adds the user to the primary group. After creating the user, you can manually add the user to any desired additional group.

## Example

The following command creates a local UNIX user named johnm (full name "John Miller") on the SVM named vs1. The user has the ID 123 and the primary group ID 100.

```
node::> vserver services name-service unix-user create -vserver vs1 -user johnm -id 123
-primary-gid 100 -full-name "John Miller"
```

## Load local UNIX users from a URI

As an alternative to manually creating individual local UNIX users in SVMs, you can simplify the task by loading a list of local UNIX users into SVMs from a uniform resource identifier (URI) (`vserver services name-service unix-user load-from-uri`).

## Steps

1. Create a file containing the list of local UNIX users you want to load.

The file must contain user information in the UNIX /etc/passwd format:

```
user_name: password: user_ID: group_ID: full_name
```

The command discards the value of the *password* field and the values of the fields after the *full\_name* field (*home\_directory* and *shell*).

The maximum supported file size is 2.5 MB.

2. Verify that the list does not contain any duplicate information.

If the list contains duplicate entries, loading the list fails with an error message.

3. Copy the file to a server.

The server must be reachable by the storage system over HTTP, HTTPS, FTP, or FTPS.

4. Determine what the URI for the file is.

The URI is the address you provide to the storage system to indicate where the file is located.

5. Load the file containing the list of local UNIX users into SVMs from the URI:

```
vserver services name-service unix-user load-from-uri -vserver vserver_name
-uri {ftp|http|ftps|https}://uri -overwrite {true|false}
```

-overwrite {true|false} specifies whether to overwrite entries. The default is false.

#### Example

The following command loads a list of local UNIX users from the URI `ftp://ftp.example.com/passwd` into the SVM named vs1. Existing users on the SVM are not overwritten by information from the URI.

```
node::> vserver services name-service unix-user load-from-uri -vserver vs1
-uri ftp://ftp.example.com/passwd -overwrite false
```

#### Create a local UNIX group

You can use the `vserver services name-service unix-group create` command to create UNIX groups that are local to the SVM. Local UNIX groups are used with local UNIX users.

#### Step

1. Create a local UNIX group:

```
vserver services name-service unix-group create -vserver vserver_name -name
group_name -id integer
```

`-name group_name` specifies the group name. The length of the group name must be 64 characters or fewer.

`-id integer` specifies the group ID that you assign.

#### Example

The following command creates a local group named eng on the SVM named vs1. The group has the ID 101.

```
vs1::> vserver services name-service unix-group create -vserver vs1 -name
eng -id 101
```

#### Add a user to a local UNIX group

You can use the `vserver services name-service unix-group adduser` command to add a user to a supplemental UNIX group that is local to the SVM.

#### Step

1. Add a user to a local UNIX group:

```
vserver services name-service unix-group adduser -vserver vserver_name -name group_name -username user_name
```

-name *group\_name* specifies the name of the UNIX group to add the user to in addition to the user's primary group.

### Example

The following command adds a user named max to a local UNIX group named eng on the SVM named vs1:

```
vs1::> vserver services name-service unix-group adduser -vserver vs1 -name eng -username max
```

### Load local UNIX groups from a URI

As an alternative to manually creating individual local UNIX groups, you can load a list of local UNIX groups into SVMs from a uniform resource identifier (URI) by using the `vserver services name-service unix-group load-from-uri` command.

#### Steps

1. Create a file containing the list of local UNIX groups you want to load.

The file must contain group information in the UNIX `/etc/group` format:

```
group_name: password: group_ID: comma_separated_list_of_users
```

The command discards the value of the `password` field.

The maximum supported file size is 1 MB.

The maximum length of each line in the group file is 32,768 characters.

2. Verify that the list does not contain any duplicate information.

The list must not contain duplicate entries, or else loading the list fails. If there are entries already present in the SVM, you must either set the `-overwrite` parameter to `true` to overwrite all existing entries with the new file, or ensure that the new file does not contain any entries that duplicate existing entries.

3. Copy the file to a server.

The server must be reachable by the storage system over HTTP, HTTPS, FTP, or FTPS.

4. Determine what the URI for the file is.

The URI is the address you provide to the storage system to indicate where the file is located.

5. Load the file containing the list of local UNIX groups into the SVM from the URI:

```
vserver services name-service unix-group load-from-uri -vserver vserver_name -uri {ftp|http|ftps|https}://uri -overwrite {true|false}
```

`-overwrite {true|false}` specifies whether to overwrite entries. The default is `false`. If you specify this parameter as `true`, ONTAP replaces the entire existing local UNIX group database of the specified SVM with the entries from the file you are loading.

## Example

The following command loads a list of local UNIX groups from the URI `ftp://ftp.example.com/group` into the SVM named `vs1`. Existing groups on the SVM are not overwritten by information from the URI.

```
vs1::> vserver services name-service unix-group load-from-uri -vserver vs1
-uri ftp://ftp.example.com/group -overwrite false
```

## Work with netgroups

### Working with netgroups overview

You can use netgroups for user authentication and to match clients in export policy rules. You can provide access to netgroups from external name servers (LDAP or NIS), or you can load netgroups from a uniform resource identifier (URI) into SVMs using the `vserver services name-service netgroup load` command.

### What you'll need

Before working with netgroups, you must ensure the following conditions are met:

- All hosts in netgroups, regardless of source (NIS, LDAP, or local files), must have both forward (A) and reverse (PTR) DNS records to provide consistent forward and reverse DNS lookups.

In addition, if an IP address of a client has multiple PTR records, all of those host names must be members of the netgroup and have corresponding A records.

- The names of all hosts in netgroups, regardless of their source (NIS, LDAP, or local files), must be correctly spelled and use the correct case. Case inconsistencies in host names used in netgroups can lead to unexpected behavior, such as failed export checks.
- All IPv6 addresses specified in netgroups must be shortened and compressed as specified in RFC 5952.

For example, `2011:hu9:0:0:0:3:1` must be shortened to `2011:hu9::3:1`.

### About this task

When you work with netgroups, you can perform the following operations:

- You can use the `vserver export-policy netgroup check-membership` command to help determine whether a client IP is a member of a certain netgroup.
- You can use the `vserver services name-service getxxbyyy netgrp` command to check whether a client is part of a netgroup.

The underlying service for doing the lookup is selected based on the configured name service switch order.

## Load netgroups into SVMs

One of the methods you can use to match clients in export policy rules is by using hosts listed in netgroups. You can load netgroups from a uniform resource identifier (URI) into SVMs as an alternative to using netgroups stored in external name servers (`vserver services name-service netgroup load`).

### What you'll need

Netgroup files must meet the following requirements before being loaded into an SVM:

- The file must use the same proper netgroup text file format that is used to populate NIS. ONTAP checks the netgroup text file format before loading it. If the file contains errors, it will not be loaded and a message is displayed indicating the corrections you have to perform in the file. After correcting the errors, you can reload the netgroup file into the specified SVM.
- Any alphabetic characters in host names in the netgroup file should be lowercase.
- The maximum supported file size is 5 MB.
- The maximum supported level for nesting netgroups is 1000.
- Only primary DNS host names can be used when defining host names in the netgroup file.

To avoid export access issues, host names should not be defined using DNS CNAME or round robin records.

- The user and domain portions of triples in the netgroup file should be kept empty because ONTAP does not support them.

Only the host/IP part is supported.

### About this task

ONTAP supports netgroup-by-host searches for the local netgroup file. After you load the netgroup file, ONTAP automatically creates a `netgroup.byhost` map to enable netgroup-by-host searches. This can significantly speed up local netgroup searches when processing export policy rules to evaluate client access.

### Step

1. Load netgroups into SVMs from a URI:

```
vserver services name-service netgroup load -vserver vserver_name -source
{ftp|http|ftps|https}://uri
```

Loading the netgroup file and building the `netgroup.byhost` map can take several minutes.

If you want to update the netgroups, you can edit the file and load the updated netgroup file into the SVM.

### Example

The following command loads netgroup definitions into the SVM named `vs1` from the HTTP URL `http://intranet/downloads/corp-netgroup`:

```
vs1::> vserver services name-service netgroup load -vserver vs1
-source http://intranet/downloads/corp-netgroup
```

## Verify the status of netgroup definitions

After loading netgroups into the SVM, you can use the `vserver services name-service netgroup status` command to verify the status of netgroup definitions. This enables you to determine whether netgroup definitions are consistent on all of the nodes that back the SVM.

### Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Verify the status of netgroup definitions:

```
vserver services name-service netgroup status
```

You can display additional information in a more detailed view.

3. Return to the admin privilege level:

```
set -privilege admin
```

### Example

After the privilege level is set, the following command displays netgroup status for all SVMs:

```

vs1::> set -privilege advanced

Warning: These advanced commands are potentially dangerous; use them only
when
 directed to do so by technical support.
Do you wish to continue? (y or n): y

vs1::*> vserver services name-service netgroup status

```

#### Create an NIS domain configuration

If a Network Information Service (NIS) is used in your environment for name services, you must create an NIS domain configuration for the SVM by using the `vserver services name-service nis-domain create` command.

#### What you'll need

All configured NIS servers must be available and reachable before you configure the NIS domain on the SVM.

If you plan to use NIS for directory searches, the maps in your NIS servers cannot have more than 1,024 characters for each entry. Do not specify the NIS server that does not comply with this limit. Otherwise, client access dependent on NIS entries might fail.

#### About this task

You can create multiple NIS domains. However, you can only use one that is set to `active`.

If your NIS database contains a `netgroup.byhost` map, ONTAP can use it for quicker searches. The `netgroup.byhost` and `netgroup` maps in the directory must be kept in sync at all times to avoid client access issues. Beginning with ONTAP 9.7, NIS `netgroup.byhost` entries can be cached using the `vserver services name-service nis-domain netgroup-database` commands.

Using NIS for host name resolution is not supported.

#### Steps

1. Create an NIS domain configuration:

```
vserver services name-service nis-domain create -vserver vs1 -domain
domain_name -active true -servers IP_addresses
```

You can specify up to 10 NIS servers.

Beginning with ONTAP 9.2, the field `-nis-servers` replaces the field `-servers`. This new field can take either a hostname or an IP address for the NIS server.

## 2. Verify that the domain is created:

```
vserver services name-service nis-domain show
```

### Example

The following command creates and makes an active NIS domain configuration for an NIS domain called `nisdomain` on the SVM named `vs1` with an NIS server at IP address `192.0.2.180`:

```
vs1::> vserver services name-service nis-domain create -vserver vs1
-domain nisdomain -active true -nis-servers 192.0.2.180
```

### Use LDAP

#### Overview of using LDAP

If LDAP is used in your environment for name services, you need to work with your LDAP administrator to determine requirements and appropriate storage system configurations, then enable the SVM as an LDAP client.

Beginning with ONTAP 9.10.1, LDAP channel binding is supported by default for both Active Directory and name services LDAP connections. ONTAP will try channel binding with LDAP connections only if Start-TLS or LDAPS is enabled along with session security set to either sign or seal. To disable or reenable LDAP channel binding with name servers, use the `-try-channel-binding` parameter with the `ldap client modify` command.

For more information, see

[2020 LDAP channel binding and LDAP signing requirements for Windows](#).

- Before configuring LDAP for ONTAP, you should verify that your site deployment meets best practices for LDAP server and client configuration. In particular, the following conditions must be met:
  - The domain name of the LDAP server must match the entry on the LDAP client.
  - The LDAP user password hash types supported by the LDAP server must include those supported by ONTAP:
    - CRYPT (all types) and SHA-1 (SHA, SSHA).
    - Beginning with ONTAP 9.8, SHA-2 hashes (SHA-256, SSH-384, SHA-512, SSHA-256, SSHA-384, and SSHA-512) are also supported.
  - If the LDAP server requires session security measures, you must configure them in the LDAP client.

The following session security options are available:

- LDAP signing (provides data integrity checking) and LDAP signing and sealing (provides data integrity checking and encryption)
- START TLS
- LDAPS (LDAP over TLS or SSL)
- To enable signed and sealed LDAP queries, the following services must be configured:
  - LDAP servers must support the GSSAPI (Kerberos) SASL mechanism.
  - LDAP servers must have DNS A/AAAA records as well as PTR records set up on the DNS server.
  - Kerberos servers must have SRV records present on the DNS server.
- To enable START TLS or LDAPS, the following points should be considered.
  - It is a NetApp best practice to use Start TLS rather than LDAPS.
  - If LDAPS is used, the LDAP server must be enabled for TLS or for SSL in ONTAP 9.5 and later. SSL is not supported in ONTAP 9.0-9.4.
  - A certificate server must already be configured in the domain.
- To enable LDAP referral chasing (in ONTAP 9.5 and later), the following conditions must be satisfied:
  - Both domains should be configured with one of the following trust relationships:
    - Two-way
    - One-way, where the primary trusts the referral domain
    - Parent-child
  - DNS must be configured to resolve all referred server names.
  - Domain passwords should be same to authenticate when --bind-as-cifs-server set to true.

The following configurations are not supported with LDAP referral chasing.

- For all ONTAP versions:
  - LDAP clients on an admin SVM
- For ONTAP 9.8 and earlier (they are supported in 9.9.1 and later):
  - LDAP signing and sealing (the `-session-security` option)
  - Encrypted TLS connections (the `-use-start-tls` option)
  - Communications over LDAPS port 636 (the `-use-ldaps-for-ad-ldap` option)

- You must enter an LDAP schema when configuring the LDAP client on the SVM.

In most cases, one of the default ONTAP schemas will be appropriate. However, if the LDAP schema in your environment differs from these, you must create a new LDAP client schema for ONTAP before creating the LDAP client. Consult with your LDAP administrator about requirements for your environment.

- Using LDAP for host name resolution is not supported.

For additional information, see [NetApp Technical Report 4835: How to Configure LDAP in ONTAP](#).

#### Create a new LDAP client schema

If the LDAP schema in your environment differs from the ONTAP defaults, you must

create a new LDAP client schema for ONTAP before creating the LDAP client configuration.

#### About this task

Most LDAP servers can use the default schemas provided by ONTAP:

- MS-AD-BIS (the preferred schema for most Windows 2012 and later AD servers)
- AD-IDMU (Windows 2008, Windows 2012 and later AD servers)
- AD-SFU (Windows 2003 and earlier AD servers)
- RFC-2307 (UNIX LDAP servers)

If you need to use a non-default LDAP schema, you must create it before creating the LDAP client configuration. Consult with your LDAP administrator before creating a new schema.

The default LDAP schemas provided by ONTAP cannot be modified. To create a new schema, you create a copy and then modify the copy accordingly.

#### Steps

1. Display the existing LDAP client schema templates to identify the one you want to copy:

```
vserver services name-service ldap client schema show
```

2. Set the privilege level to advanced:

```
set -privilege advanced
```

3. Make a copy of an existing LDAP client schema:

```
vserver services name-service ldap client schema copy -vserver vserver_name
-schema existing_schema_name -new-schema-name new_schema_name
```

4. Modify the new schema and customize it for your environment:

```
vserver services name-service ldap client schema modify
```

5. Return to the admin privilege level:

```
set -privilege admin
```

#### Install the self-signed root CA certificate on the SVM

If LDAP authentication with TLS is required when binding to LDAP servers, you must first install the self-signed root CA certificate on the SVM.

#### About this task

When LDAP over TLS is enabled, the ONTAP LDAP client on the SVM does not support revoked certificates in ONTAP 9.0 and 9.1.

Beginning with ONTAP 9.2, all applications within ONTAP that use TLS communications can check digital certificate status using Online Certificate Status Protocol (OCSP). If OCSP is enabled for LDAP over TLS, revoked certificates are rejected and the connection fails.

## Steps

1. Install the self-signed root CA certificate:

- a. Begin the certificate installation:

```
security certificate install -vserver vserver_name -type server-ca
```

The console output displays the following message:

```
Please enter Certificate: Press <Enter> when done
```

- b. Open the certificate .pem file with a text editor, copy the certificate, including the lines beginning with -----BEGIN CERTIFICATE----- and ending with -----END CERTIFICATE-----, and then paste the certificate after the command prompt.
- c. Verify that the certificate is displayed correctly.
- d. Complete the installation by pressing Enter.

2. Verify that the certificate is installed:

```
security certificate show -vserver vserver_name
```

## Create an LDAP client configuration

If you want ONTAP to access the external LDAP servers in your environment, you must first set up an LDAP client on the storage system.

### What you'll need

One of the first three servers in the AD-domain resolved list must be up and serving data. Otherwise, this task fails.

There are multiple servers, out of which more than two servers are down at any point of time.

## Steps

1. Consult with your LDAP administrator to determine the appropriate configuration values for the vserver services name-service ldap client create command:
  - a. Specify a domain-based or an address-based connection to LDAP servers.

The `-ad-domain` and `-servers` options are mutually exclusive.

- Use the `-ad-domain` option to enable LDAP server discovery in the Active Directory domain.

You can use the `-preferred-ad-servers` option to specify one or more preferred Active Directory servers by IP address in a comma-delimited list. After the client is created, you can modify this list by using the `vserver services name-service ldap client modify` command.

- Use the `-servers` option to specify one or more LDAP servers (AD or UNIX) by IP address in a comma-delimited list.

The `-servers` option is deprecated in ONTAP 9.2. Beginning with ONTAP 9.2, the `-ldap-servers` field replaces the `-servers` field. This new field can take either a host name or an IP address for the LDAP server.

b. Specify a default or custom LDAP schema.

Most LDAP servers can use the default read-only schemas that are provided by ONTAP. It is best to use those default schemas unless there is a requirement to do otherwise. If so, you can create your own schema by copying a default schema (they are read-only), and then modifying the copy.

Default schemas:

- MS-AD-BIS

Based on RFC-2307bis, this is the preferred LDAP schema for most standard Windows 2012 and later LDAP deployments.

- AD-IDMU

Based on Active Directory Identity Management for UNIX, this schema is appropriate for most Windows 2008, Windows 2012, and later AD servers.

- AD-SFU

Based on Active Directory Services for UNIX, this schema is appropriate for most Windows 2003 and earlier AD servers.

- RFC-2307

Based on RFC-2307 (*An Approach for Using LDAP as a Network Information Service*), this schema is appropriate for most UNIX AD servers.

c. Select bind values.

- `-min-bind-level {anonymous|simple|sasl}` specifies the minimum bind authentication level.

The default value is **anonymous**.

- `-bind-dn LDAP_DN` specifies the bind user.

For Active Directory servers, you must specify the user in the account (DOMAIN\user) or principal (`user@domain.com`) form. Otherwise, you must specify the user in distinguished name (CN=user,DC=domain,DC=com) form.

- `-bind-password password` specifies the bind password.

d. Select session security options, if required.

You can enable either LDAP signing and sealing or LDAP over TLS if required by the LDAP server.

- `--session-security {none|sign|seal}`

You can enable signing (sign, data integrity), signing and sealing (seal, data integrity and encryption), or neither (none, no signing or sealing). The default value is `none`.

You should also set `-min-bind-level {sasl}` unless you want the bind authentication to fall back to **anonymous** or **simple** if the signing and sealing bind fails.

- `-use-start-tls {true|false}`

If set to **true** and the LDAP server supports it, the LDAP client uses an encrypted TLS connection to the server. The default value is **false**. You must install a self-signed root CA certificate of the LDAP server to use this option.

If the SVM has a SMB server added to a domain and the LDAP server is one of the domain controllers of the home-domain of the SMB server, then you can modify the `-session-security-for-ad-ldap` option by using the `vserver cifs security modify` command.

e. Select port, query, and base values.

The default values are recommended, but you must verify with your LDAP administrator that they are appropriate for your environment.

- `-port port` specifies the LDAP server port.

The default value is 389.

If you plan to use Start TLS to secure the LDAP connection, you must use the default port 389. Start TLS begins as a plaintext connection over the LDAP default port 389, and that connection is then upgraded to TLS. If you change the port, Start TLS fails.

- `-query-timeout integer` specifies the query timeout in seconds.

The allowed range is from 1 through 10 seconds. The default value is 3 seconds.

- `-base-dn LDAP_DN` specifies the base DN.

Multiple values can be entered if needed (for example, if LDAP referral chasing is enabled). The default value is "" (root).

- `-base-scope {base|onelevel|subtree}` specifies the base search scope.

The default value is `subtree`.

- `-referral-enabled {true|false}` specifies whether LDAP referral chasing is enabled.

Beginning with ONTAP 9.5, this allows the ONTAP LDAP client to refer look-up requests to other LDAP servers if an LDAP referral response is returned by the primary LDAP server indicating that the desired records are present on referred LDAP servers. The default value is **false**.

To search for records present in the referred LDAP servers, the `base-dn` of the referred records must be added to the `base-dn` as part of LDAP client configuration.

2. Create an LDAP client configuration on the SVM:

```
vserver services name-service ldap client create -vserver vserver_name -client -config client_config_name {-servers LDAP_server_list | -ad-domain ad_domain}
```

```
-preferred-ad-servers preferred_ad_server_list -schema schema -port 389 -query
-timeout 3 -min-bind-level {anonymous|simple|sasl} -bind-dn LDAP_DN -bind
-password password -base-dn LDAP_DN -base-scope subtree -session-security
{none|sign|seal} [-referral-enabled {true|false}]
```

You must provide the SVM name when creating an LDAP client configuration.

3. Verify that the LDAP client configuration is created successfully:

```
vserver services name-service ldap client show -client-config
client_config_name
```

## Examples

The following command creates a new LDAP client configuration named `ldap1` for the SVM `vs1` to work with an Active Directory server for LDAP:

```
cluster1::> vserver services name-service ldap client create -vserver vs1
-client-config ldapclient1 -ad-domain addomain.example.com -schema AD-SFU
-port 389 -query-timeout 3 -min-bind-level simple -base-dn
DC=addomain,DC=example,DC=com -base-scope subtree -preferred-ad-servers
172.17.32.100
```

The following command creates a new LDAP client configuration named `ldap1` for the SVM `vs1` to work with an Active Directory server for LDAP on which signing and sealing is required:

```
cluster1::> vserver services name-service ldap client create -vserver vs1
-client-config ldapclient1 -ad-domain addomain.example.com -schema AD-SFU
-port 389 -query-timeout 3 -min-bind-level sasl -base-dn
DC=addomain,DC=example,DC=com -base-scope subtree -preferred-ad-servers
172.17.32.100 -session-security seal
```

The following command creates a new LDAP client configuration named `ldap1` for the SVM `vs1` to work with an Active Directory server for LDAP where LDAP referral chasing is required:

```
cluster1::> vserver services name-service ldap client create -vserver vs1
-client-config ldapclient1 -ad-domain addomain.example.com -schema AD-SFU
-port 389 -query-timeout 3 -min-bind-level sasl -base-dn
"DC=adbasedomain,DC=example1,DC=com; DC=adrefdomain,DC=example2,DC=com"
-base-scope subtree -preferred-ad-servers 172.17.32.100 -referral-enabled
true
```

The following command modifies the LDAP client configuration named `ldap1` for the SVM `vs1` by specifying the base DN:

```
cluster1::> vserver services name-service ldap client modify -vserver vs1
-client-config ldap1 -base-dn CN=Users,DC=addomain,DC=example,DC=com
```

The following command modifies the LDAP client configuration named ldap1 for the SVM vs1 by enabling referral chasing:

```
cluster1::> vserver services name-service ldap client modify -vserver vs1
-client-config ldap1 -base-dn "DC=adbasedomain,DC=example1,DC=com;
DC=adrefdomain,DC=example2,DC=com" -referral-enabled true
```

### Associate the LDAP client configuration with SVMs

To enable LDAP on an SVM, you must use the `vserver services name-service ldap create` command to associate an LDAP client configuration with the SVM.

#### What you'll need

- An LDAP domain must already exist within the network and must be accessible to the cluster that the SVM is located on.
- An LDAP client configuration must exist on the SVM.

#### Steps

1. Enable LDAP on the SVM:

```
vserver services name-service ldap create -vserver vserver_name -client-config
client_config_name
```

Beginning with ONTAP 9.2, the `vserver services name-service ldap create` command performs an automatic configuration validation and reports an error message if ONTAP is unable to contact the name server.

The following command enables LDAP on the "vs1" SVM and configures it to use the "ldap1" LDAP client configuration:

```
cluster1::> vserver services name-service ldap create -vserver vs1
-client-config ldap1 -client-enabled true
```

2. Validate the status of the name servers by using the `vserver services name-service ldap check` command.

The following command validates LDAP servers on the SVM vs1.

```

cluster1::> vserver services name-service ldap check -vserver vs1

| Vserver: vs1
| Client Configuration Name: c1
| LDAP Status: up
| LDAP Status Details: Successfully connected to LDAP server
"10.11.12.13".

```

The name service check command is available beginning with ONTAP 9.2.

### Verify LDAP sources in the name service switch table

You must verify that LDAP sources for name services are listed correctly in the name service switch table for the SVM.

#### Steps

1. Display the current name service switch table contents:

```
vserver services name-service ns-switch show -vserver svm_name
```

The following command shows the results for the SVM My\_SVM:

```

ie3220-a::> vserver services name-service ns-switch show -vserver My_SVM
 Source
Vserver Database Order

My_SVM hosts files,
 dns
My_SVM group files,ldap
My_SVM passwd files,ldap
My_SVM netgroup files
My_SVM namemap files
5 entries were displayed.

```

**namemap** specifies the sources to search for name mapping information and in what order. In a UNIX-only environment, this entry is not necessary. Name mapping is only required in a mixed environment using both UNIX and Windows.

2. Update the ns-switch entry as appropriate:

| If you want to update the ns-switch entry for... | Enter the command...                                                                                                         |
|--------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------|
| User information                                 | <pre>vserver services name-service ns- switch modify -vserver <i>vserver_name</i> -database passwd -sources ldap,files</pre> |

| If you want to update the ns-switch entry for... | Enter the command...                                                                                        |
|--------------------------------------------------|-------------------------------------------------------------------------------------------------------------|
| Group information                                | vserver services name-service ns-switch modify -vserver vserver_name -database group -sources ldap,files    |
| Netgroup information                             | vserver services name-service ns-switch modify -vserver vserver_name -database netgroup -sources ldap,files |

## Use Kerberos with NFS for strong security

### Overview of using Kerberos with NFS for strong security

If Kerberos is used in your environment for strong authentication, you need to work with your Kerberos administrator to determine requirements and appropriate storage system configurations, and then enable the SVM as a Kerberos client.

Your environment should meet the following guidelines:

- Your site deployment should follow best practices for Kerberos server and client configuration before you configure Kerberos for ONTAP.
- If possible, use NFSv4 or later if Kerberos authentication is required.

NFSv3 can be used with Kerberos. However, the full security benefits of Kerberos are only realized in ONTAP deployments of NFSv4 or later.

- To promote redundant server access, Kerberos should be enabled on several data LIFs on multiple nodes in the cluster using the same SPN.
- When Kerberos is enabled on the SVM, one of the following security methods must be specified in export rules for volumes or qtrees depending on your NFS client configuration.
  - krb5 (Kerberos v5 protocol)
  - krb5i (Kerberos v5 protocol with integrity checking using checksums)
  - krb5p (Kerberos v5 protocol with privacy service)

In addition to the Kerberos server and clients, the following external services must be configured for ONTAP to support Kerberos:

- Directory service

You should use a secure directory service in your environment, such as Active Directory or OpenLDAP, that is configured to use LDAP over SSL/TLS. Do not use NIS, whose requests are sent in clear text and are hence not secure.

- NTP

You must have a working time server running NTP. This is necessary to prevent Kerberos authentication failure due to time skew.

- Domain name resolution (DNS)

Each UNIX client and each SVM LIF must have a proper service record (SRV) registered with the KDC under forward and reverse lookup zones. All participants must be properly resolvable via DNS.

#### Verify permissions for Kerberos configuration

Kerberos requires that certain UNIX permissions be set for the SVM root volume and for local users and groups.

#### Steps

1. Display the relevant permissions on the SVM root volume:

```
volume show -volume root_vol_name-fields user,group,unix-permissions
```

The root volume of the SVM must have the following configuration:

| Name...          | Setting...   |
|------------------|--------------|
| UID              | root or ID 0 |
| GID              | root or ID 0 |
| UNIX permissions | 755          |

If these values are not shown, use the `volume modify` command to update them.

2. Display the local UNIX users:

```
vserver services name-service unix-user show -vserver vserver_name
```

The SVM must have the following UNIX users configured:

| User name | User ID | Primary group ID | Comment                                                                                                                                                                                                                       |
|-----------|---------|------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| nfs       | 500     | 0                | <p>Required for GSS INIT phase.</p> <p>The first component of the NFS client user SPN is used as the user.</p> <p>The nfs user is not required if a Kerberos-UNIX name mapping exists for the SPN of the NFS client user.</p> |
| root      | 0       | 0                | Required for mounting.                                                                                                                                                                                                        |

If these values are not shown, you can use the `vserver services name-service unix-user modify` command to update them.

### 3. Display the local UNIX groups:

```
vserver services name-service unix-group show -vserver vserver_name
```

The SVM must have the following UNIX groups configured:

| Group name | Group ID |
|------------|----------|
| daemon     | 1        |
| root       | 0        |

If these values are not shown, you can use the `vserver services name-service unix-group modify` command to update them.

## Create an NFS Kerberos realm configuration

If you want ONTAP to access external Kerberos servers in your environment, you must first configure the SVM to use an existing Kerberos realm. To do so, you need to gather configuration values for the Kerberos KDC server, and then use the `vserver nfs kerberos realm create` command to create the Kerberos realm configuration on an SVM.

### What you'll need

The cluster administrator should have configured NTP on the storage system, client, and KDC server to avoid authentication issues. Time differences between a client and server (clock skew) are a common cause of authentication failures.

### Steps

1. Consult with your Kerberos administrator to determine the appropriate configuration values to supply with the `vserver nfs kerberos realm create` command.
2. Create a Kerberos realm configuration on the SVM:

```
vserver nfs kerberos realm create -vserver vserver_name -realm realm_name
{AD_KDC_server_values |AD_KDC_server_values} -comment "text"
```

3. Verify that the Kerberos realm configuration was created successfully:

```
vserver nfs kerberos realm show
```

### Examples

The following command creates an NFS Kerberos realm configuration for the SVM vs1 that uses a Microsoft Active Directory server as the KDC server. The Kerberos realm is AUTH.EXAMPLE.COM. The Active Directory server is named ad-1 and its IP address is 10.10.8.14. The permitted clock skew is 300 seconds (the default). The IP address of the KDC server is 10.10.8.14, and its port number is 88 (the default). "Microsoft Kerberos config" is the comment.

```
vs1::> vserver nfs kerberos realm create -vserver vs1 -realm
AUTH.EXAMPLE.COM -adserver-name ad-1
-adserver-ip 10.10.8.14 -clock-skew 300 -kdc-ip 10.10.8.14 -kdc-port 88
-kdc-vendor Microsoft
-comment "Microsoft Kerberos config"
```

The following command creates an NFS Kerberos realm configuration for the SVM vs1 that uses an MIT KDC. The Kerberos realm is SECURITY.EXAMPLE.COM. The permitted clock skew is 300 seconds. The IP address of the KDC server is 10.10.9.1, and its port number is 88. The KDC vendor is Other to indicate a UNIX vendor. The IP address of the administrative server is 10.10.9.1, and its port number is 749 (the default). The IP address of the password server is 10.10.9.1, and its port number is 464 (the default). "UNIX Kerberos config" is the comment.

```
vs1::> vserver nfs kerberos realm create -vserver vs1 -realm
SECURITY.EXAMPLE.COM. -clock-skew 300
-kdc-ip 10.10.9.1 -kdc-port 88 -kdc-vendor Other -adminserver-ip 10.10.9.1
-adminserver-port 749
-passwordserver-ip 10.10.9.1 -passwordserver-port 464 -comment "UNIX
Kerberos config"
```

#### Configure NFS Kerberos permitted encryption types

By default, ONTAP supports the following encryption types for NFS Kerberos: DES, 3DES, AES-128, and AES-256. You can configure the permitted encryption types for each SVM to suit the security requirements for your particular environment by using the `vserver nfs modify` command with the `-permitted-enc-types` parameter.

#### About this task

For greatest client compatibility, ONTAP supports both weak DES and strong AES encryption by default. This means, for example, that if you want to increase security and your environment supports it, you can use this procedure to disable DES and 3DES and require clients to use only AES encryption.

You should use the strongest encryption available. For ONTAP, that is AES-256. You should confirm with your KDC administrator that this encryption level is supported in your environment.

- Enabling or disabling AES entirely (both AES-128 and AES-256) on SVMs is disruptive because it destroys the original DES principal/keytab file, thereby requiring that the Kerberos configuration be disabled on all LIFs for the SVM.

Before making this change, you should verify that NFS clients do not rely on AES encryption on the SVM.

- Enabling or disabling DES or 3DES does not require any changes to the Kerberos configuration on LIFs.

#### Step

- Enable or disable the permitted encryption type you want:

| If you want to enable or disable... | Follow these steps...                                                                                                                                                                                                                                                                                                                                         |
|-------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| DES or 3DES                         | <p>a. Configure the NFS Kerberos permitted encryption types of the SVM:</p> <pre>vserver nfs modify -vserver vserver_name -permitted-enc-types encryption_types</pre> <p>Separate multiple encryption types with a comma.</p> <p>b. Verify that the change was successful:</p> <pre>vserver nfs show -vserver vserver_name -fields permitted-enc- types</pre> |

| If you want to enable or disable... | Follow these steps...                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
|-------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| AES-128 or AES-256                  | <p>a. Identify on which SVM and LIF Kerberos is enabled:</p> <pre>vserver nfs kerberos interface show</pre> <p>b. Disable Kerberos on all LIFs on the SVM whose NFS Kerberos permitted encryption type you want to modify:</p> <pre>vserver nfs kerberos interface disable -lif <i>lif_name</i></pre> <p>c. Configure the NFS Kerberos permitted encryption types of the SVM:</p> <pre>vserver nfs modify -vserver <i>vserver_name</i> -permitted-enc-types <i>encryption_types</i></pre> <p>Separate multiple encryption types with a comma.</p> <p>d. Verify that the change was successful:</p> <pre>vserver nfs show -vserver <i>vserver_name</i> -fields permitted-enc-types</pre> <p>e. Reenable Kerberos on all LIFs on the SVM:</p> <pre>vserver nfs kerberos interface enable -lif <i>lif_name</i> -spn <i>service_principal_name</i></pre> <p>f. Verify that Kerberos is enabled on all LIFs:</p> <pre>vserver nfs kerberos interface show</pre> |

#### Enable Kerberos on a data LIF

You can use the `vserver nfs kerberos interface enable` command to enable Kerberos on a data LIF. This enables the SVM to use Kerberos security services for NFS.

#### About this task

If you are using an Active Directory KDC, the first 15 characters of any SPNs used must be unique across SVMs within a realm or domain.

#### Steps

1. Create the NFS Kerberos configuration:

```
vserver nfs kerberos interface enable -vserver vserver_name -lif
```

```
logical_interface -spn service_principal_name
```

ONTAP requires the secret key for the SPN from the KDC to enable the Kerberos interface.

For Microsoft KDCs, the KDC is contacted and a user name and password prompt are issued at the CLI to obtain the secret key. If you need to create the SPN in a different OU of the Kerberos realm, you can specify the optional **-ou** parameter.

For non-Microsoft KDCs, the secret key can be obtained using one of two methods:

| If you...                                                                                            | You must also include the following parameter with the command... |
|------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------|
| Have the KDC administrator credentials to retrieve the key directly from the KDC                     | <code>-admin-username kdc_admin_username</code>                   |
| Do not have the KDC administrator credentials but have a keytab file from the KDC containing the key | <code>-keytab-uri {ftp http}://uri</code>                         |

2. Verify that Kerberos was enabled on the LIF:

```
vserver nfs kerberos-config show
```

3. Repeat steps 1 and 2 to enable Kerberos on multiple LIFs.

#### Example

The following command creates and verifies an NFS Kerberos configuration for the SVM named vs1 on the logical interface ves03-d1, with the SPN nfs/ves03-d1.lab.example.com@TEST.LAB.EXAMPLE.COM in the OU lab2ou:

```
vs1::> vserver nfs kerberos interface enable -lif ves03-d1 -vserver vs2
-spn nfs/ves03-d1.lab.example.com@TEST.LAB.EXAMPLE.COM -ou "ou=lab2ou"

vs1::>vserver nfs kerberos-config show
Logical
Vserver Interface Address Kerberos SPN
----- ----- -----
vs0 ves01-a1 10.10.10.30 disabled -
vs2 ves01-d1 10.10.10.40 enabled nfs/ves03-
d1.lab.example.com@TEST.LAB.EXAMPLE.COM
2 entries were displayed.
```

## Add storage capacity to an NFS-enabled SVM

## Add storage capacity to an NFS-enabled SVM overview

To add storage capacity to an NFS-enabled SVM, you must create a volume or qtree to provide a storage container, and create or modify an export policy for that container. You can then verify NFS client access from the cluster and test access from client systems.

### What you'll need

- NFS must be completely set up on the SVM.
- The default export policy of the SVM root volume must contain a rule that permits access to all clients.
- Any updates to your name services configuration must be complete.
- Any additions or modifications to a Kerberos configuration must be complete.

### Create an export policy

Before creating export rules, you must create an export policy to hold them. You can use the `vserver export-policy create` command to create an export policy.

#### Steps

1. Create an export policy:

```
vserver export-policy create -vserver vserver_name -policyname policy_name
```

The policy name can be up to 256 characters long.

2. Verify that the export policy was created:

```
vserver export-policy show -policyname policy_name
```

#### Example

The following commands create and verify the creation of an export policy named `exp1` on the SVM named `vs1`:

```
vs1::> vserver export-policy create -vserver vs1 -policyname exp1

vs1::> vserver export-policy show -policyname exp1
Vserver Policy Name

vs1 exp1
```

### Add a rule to an export policy

Without rules, the export policy cannot provide client access to data. To create a new export rule, you must identify clients and select a client match format, select the access and security types, specify an anonymous user ID mapping, select a rule index number, and select the access protocol. You can then use the `vserver export-policy rule create` command to add the new rule to an export policy.

## What you'll need

- The export policy you want to add the export rules to must already exist.
- DNS must be correctly configured on the data SVM and DNS servers must have correct entries for NFS clients.

This is because ONTAP performs DNS lookups using the DNS configuration of the data SVM for certain client match formats, and failures in export policy rule matching can prevent client data access.

- If you are authenticating with Kerberos, you must have determined which of the following security methods is used on your NFS clients:
  - krb5 (Kerberos V5 protocol)
  - krb5i (Kerberos V5 protocol with integrity checking using checksums)
  - krb5p (Kerberos V5 protocol with privacy service)

## About this task

It is not necessary to create a new rule if an existing rule in an export policy covers your client match and access requirements.

If you are authenticating with Kerberos and if all volumes of the SVM are accessed over Kerberos, you can set the export rule options `-rorule`, `-rwrule`, and `-superuser` for the root volume to `krb5`, `krb5i`, or `krb5p`.

## Steps

1. Identify the clients and the client match format for the new rule.

The `-clientmatch` option specifies the clients to which the rule applies. Single or multiple client match values can be specified; specifications of multiple values must be separated by commas. You can specify the match in any of the following formats:

| Client match format                                           | Example                                                                                                     |
|---------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------|
| Domain name preceded by the "." character                     | <code>.example.com</code> or<br><code>.example.com,.example.net,...</code>                                  |
| Host name                                                     | <code>host1</code> or <code>host1,host2, ...</code>                                                         |
| IPv4 address                                                  | <code>10.1.12.24</code> or <code>10.1.12.24,10.1.12.25, ...</code>                                          |
| IPv4 address with a subnet mask expressed as a number of bits | <code>10.1.12.10/4</code> or<br><code>10.1.12.10/4,10.1.12.11/4,...</code>                                  |
| IPv4 address with a network mask                              | <code>10.1.16.0/255.255.255.0</code> or<br><code>10.1.16.0/255.255.255.0,10.1.17.0/255.255.255.0,...</code> |
| IPv6 address in dotted format                                 | <code>::1.2.3.4</code> or <code>::1.2.3.4,::1.2.3.5,...</code>                                              |

| Client match format                                                  | Example                                   |
|----------------------------------------------------------------------|-------------------------------------------|
| IPv6 address with a subnet mask expressed as a number of bits        | ff::00/32 or ff::00/32, ff::01/32, ...    |
| A single netgroup with the netgroup name preceded by the @ character | @netgroup1 or @netgroup1, @netgroup2, ... |

You can also combine types of client definitions; for example, .example.com, @netgroup1.

When specifying IP addresses, note the following:

- Entering an IP address range, such as 10.1.12.10-10.1.12.70, is not allowed.

Entries in this format are interpreted as a text string and treated as a host name.

- When specifying individual IP addresses in export rules for granular management of client access, do not specify IP addresses that are dynamically (for example, DHCP) or temporarily (for example, IPv6) assigned.

Otherwise, the client loses access when its IP address changes.

- Entering an IPv6 address with a network mask, such as ff::12/ff::00, is not allowed.

## 2. Select the access and security types for client matches.

You can specify one or more of the following access modes to clients that authenticate with the specified security types:

- -rорule (read-only access)
- -rwrule (read-write access)
- -superuser (root access)

A client can only get read-write access for a specific security type if the export rule allows read-only access for that security type as well. If the read-only parameter is more restrictive for a security type than the read-write parameter, the client might not get read-write access. The same is true for superuser access.

You can specify a comma-separated list of multiple security types for a rule. If you specify the security type as any or never, do not specify any other security types. Choose from the following valid security types:

| When security type is set to... | A matching client can access the exported data... |
|---------------------------------|---------------------------------------------------|
| any                             | Always, regardless of incoming security type.     |

| <b>When security type is set to...</b> | <b>A matching client can access the exported data...</b>                                                                                                                                                                                                  |
|----------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| none                                   | If listed alone, clients with any security type are granted access as anonymous. If listed with other security types, clients with a specified security type are granted access and clients with any other security type are granted access as anonymous. |
| never                                  | Never, regardless of incoming security type.                                                                                                                                                                                                              |
| krb5                                   | If it is authenticated by Kerberos 5. Authentication only: The header of each request and response is signed.                                                                                                                                             |
| krb5i                                  | If it is authenticated by Kerberos 5i. Authentication and integrity: The header and body of each request and response is signed.                                                                                                                          |
| krb5p                                  | If it is authenticated by Kerberos 5p. Authentication, integrity, and privacy: The header and body of each request and response is signed, and the NFS data payload is encrypted.                                                                         |
| ntlm                                   | If it is authenticated by CIFS NTLM.                                                                                                                                                                                                                      |
| sys                                    | If it is authenticated by NFS AUTH_SYS.                                                                                                                                                                                                                   |

The recommended security type is `sys`, or if Kerberos is used, `krb5`, `krb5i`, or `krb5p`.

If you are using Kerberos with NFSv3, the export policy rule must allow `-rorule` and `-rwrule` access to `sys` in addition to `krb5`. This is because of the need to allow Network Lock Manager (NLM) access to the export.

### 3. Specify an anonymous user ID mapping.

The `-anon` option specifies a UNIX user ID or user name that is mapped to client requests that arrive with a user ID of 0 (zero), which is typically associated with the user name `root`. The default value is 65534. NFS clients typically associate user ID 65534 with the user name `nobody` (also known as *root squashing*). In ONTAP, this user ID is associated with the user `pcuser`. To disable access by any client with a user ID of 0, specify a value of 65535.

### 4. Select the rule index order.

The `-ruleindex` option specifies the index number for the rule. Rules are evaluated according to their order in the list of index numbers; rules with lower index numbers are evaluated first. For example, the rule with index number 1 is evaluated before the rule with index number 2.

| If you are adding...                 | Then...                                                                                                                                                                                                                              |
|--------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| The first rule to an export policy   | Enter 1.                                                                                                                                                                                                                             |
| Additional rules to an export policy | <p>a. Display existing rules in the policy:</p> <pre>vserver export-policy rule show -instance -policyname <i>your_policy</i></pre> <p>b. Select an index number for the new rule depending on the order it should be evaluated.</p> |

5. Select the applicable NFS access value: {nfs|nfs3|nfs4}.

nfs matches any version, nfs3 and nfs4 match only those specific versions.

6. Create the export rule and add it to an existing export policy:

```
vserver export-policy rule create -vserver vserver_name -policyname policy_name -ruleindex integer -protocol {nfs|nfs3|nfs4} -clientmatch { text | "text,text,..." } -rorule security_type -rwrule security_type -superuser security_type -anon user_ID
```

7. Display the rules for the export policy to verify that the new rule is present:

```
vserver export-policy rule show -policyname policy_name
```

The command displays a summary for that export policy, including a list of rules applied to that policy. ONTAP assigns each rule a rule index number. After you know the rule index number, you can use it to display detailed information about the specified export rule.

8. Verify that the rules applied to the export policy are configured correctly:

```
vserver export-policy rule show -policyname policy_name -vserver vserver_name -ruleindex integer
```

## Examples

The following commands create and verify the creation of an export rule on the SVM named vs1 in an export policy named rs1. The rule has the index number 1. The rule matches any client in the domain eng.company.com and the netgroup @netgroup1. The rule enables all NFS access. It enables read-only and read-write access to users that authenticated with AUTH\_SYS. Clients with the UNIX user ID 0 (zero) are anonymized unless authenticated with Kerberos.

```
vs1::> vserver export-policy rule create -vserver vs1 -policyname expl
-ruleindex 1 -protocol nfs
-clientmatch .eng.company.com,@netgroup1 -rorule sys -rwrule sys -anon
65534 -superuser krb5
```

```
vs1::> vserver export-policy rule show -policyname nfs_policy
```

| Virtual Server | Policy Name | Rule Index | Access Protocol | Client Match                       | RO Rule |
|----------------|-------------|------------|-----------------|------------------------------------|---------|
| vs1            | expl        | 1          | nfs             | eng.company.com, sys<br>@netgroup1 |         |

```
vs1::> vserver export-policy rule show -policyname expl -vserver vs1
-ruleindex 1
```

```
Vserver: vs1
Policy Name: expl
Rule Index: 1
Access Protocol: nfs
Client Match Hostname, IP Address, Netgroup, or Domain:
eng.company.com,@netgroup1
RO Access Rule: sys
RW Access Rule: sys
User ID To Which Anonymous Users Are Mapped: 65534
Superuser Security Types: krb5
Honor SetUID Bits in SETATTR: true
Allow Creation of Devices: true
```

The following commands create and verify the creation of an export rule on the SVM named vs2 in an export policy named expl2. The rule has the index number 21. The rule matches clients to members of the netgroup dev\_netgroup\_main. The rule enables all NFS access. It enables read-only access for users that authenticated with AUTH\_SYS and requires Kerberos authentication for read-write and root access. Clients with the UNIX user ID 0 (zero) are denied root access unless authenticated with Kerberos.

```

vs2::> vserver export-policy rule create -vserver vs2 -policyname expol2
 -ruleindex 21 -protocol nfs
 -clientmatch @dev_netgroup_main -rorule sys -rwrule krb5 -anon 65535
 -superuser krb5

vs2::> vserver export-policy rule show -policyname nfs_policy
Virtual Policy Rule Access Client RO
Server Name Index Protocol Match Rule
----- ----- ----- ----- ----- -----
vs2 expol2 21 nfs @dev_netgroup_main sys

vs2::> vserver export-policy rule show -policyname expol2 -vserver vs1
 -ruleindex 21

 Vserver: vs2
 Policy Name: expol2
 Rule Index: 21
 Access Protocol: nfs
Client Match Hostname, IP Address, Netgroup, or Domain:
 @dev_netgroup_main
 RO Access Rule: sys
 RW Access Rule: krb5
User ID To Which Anonymous Users Are Mapped: 65535
 Superuser Security Types: krb5
 Honor SetUID Bits in SETATTR: true
 Allow Creation of Devices: true

```

## Create a volume or qtree storage container

### Create a volume

You can create a volume and specify its junction point and other properties by using the `volume create` command.

### About this task

A volume must include a *junction path* for its data to be made available to clients. You can specify the junction path when you create a new volume. If you create a volume without specifying a junction path, you must *mount* the volume in the SVM namespace using the `volume mount` command.

### Before you begin

- NFS should be set up and running.
- The SVM security style must be UNIX.
- Beginning in ONTAP 9.13.1, you can create volumes with capacity analytics and Activity Tracking enabled. To enable capacity or Activity Tracking, issue the `volume create` command with `-analytics-state` or `-activity-tracking-state` set to on.

To learn more about capacity analytics and Activity Tracking, see [Enable File System Analytics](#).

## Steps

### 1. Create the volume with a junction point:

```
volume create -vserver svm_name -volume volume_name -aggregate aggregate_name
-size {integer[KB|MB|GB|TB|PB]} -security-style unix -user user_name_or_number
-group group_name_or_number -junction-path junction_path [-policy
export_policy_name]
```

The choices for `-junction-path` are the following:

- Directly under root, for example, `/new_vol`

You can create a new volume and specify that it be mounted directly to the SVM root volume.

- Under an existing directory, for example, `/existing_dir/new_vol`

You can create a new volume and specify that it be mounted to an existing volume (in an existing hierarchy), expressed as a directory.

If you want to create a volume in a new directory (in a new hierarchy under a new volume), for example, `/new_dir/new_vol`, then you must first create a new parent volume that is junctioned to the SVM root volume. You would then create the new child volume in the junction path of the new parent volume (new directory).

+

If you plan to use an existing export policy, you can specify it when you create the volume. You can also add an export policy later with the `volume modify` command.

### 2. Verify that the volume was created with the desired junction point:

```
volume show -vserver svm_name -volume volume_name -junction
```

## Examples

The following command creates a new volume named `users1` on the SVM `vs1.example.com` and the aggregate `aggr1`. The new volume is made available at `/users`. The volume is 750 GB in size, and its volume guarantee is of type `volume` (by default).

```
cluster1::> volume create -vserver vs1.example.com -volume users
-aggregate aggr1 -size 750g -junction-path /users
[Job 1642] Job succeeded: Successful
```

```
cluster1::> volume show -vserver vs1.example.com -volume users -junction
 Junction Junction
Vserver Volume Active Junction Path Path Source
----- -----
vs1.example.com users1 true /users RW_volume
```

The following command creates a new volume named "home4" on the SVM "vs1.example.com" and the

aggregate "aggr1". The directory /eng/ already exists in the namespace for the vs1 SVM, and the new volume is made available at /eng/home, which becomes the home directory for the /eng/ namespace. The volume is 750 GB in size, and its volume guarantee is of type volume (by default).

```
cluster1::> volume create -vserver vs1.example.com -volume home4
-aggregate aggr1 -size 750g -junction-path /eng/home
[Job 1642] Job succeeded: Successful

cluster1::> volume show -vserver vs1.example.com -volume home4 -junction
Junction Junction
Vserver Volume Active Junction Path Path Source

vs1.example.com home4 true /eng/home RW_volume
```

## Create a qtree

You can create a qtree to contain your data and specify its properties by using the `volume qtree create` command.

### What you'll need

- The SVM and the volume that will contain the new qtree must already exist.
- The SVM security style must be UNIX, and NFS should be set up and running.

### Steps

1. Create the qtree:

```
volume qtree create -vserver vserver_name { -volume volume_name -qtree
qtree_name | -qtree-path qtree_path } -security-style unix [-policy
export_policy_name]
```

You can specify the volume and qtree as separate arguments or specify the qtree path argument in the format `/vol/volume_name/_qtree_name`.

By default, qtrees inherit the export policies of their parent volume, but they can be configured to use their own. If you plan to use an existing export policy, you can specify it when you create the qtree. You can also add an export policy later with the `volume qtree modify` command.

2. Verify that the qtree was created with the desired junction path:

```
volume qtree show -vserver vserver_name { -volume volume_name -qtree
qtree_name | -qtree-path qtree_path }
```

### Example

The following example creates a qtree named qt01 located on SVM vs1.example.com that has a junction path /vol/data1:

```

cluster1::> volume qtree create -vserver vs1.example.com -qtree-path
/vol/data1/qt01 -security-style unix
[Job 1642] Job succeeded: Successful

cluster1::> volume qtree show -vserver vs1.example.com -qtree-path
/vol/data1/qt01

 Vserver Name: vs1.example.com
 Volume Name: data1
 Qtree Name: qt01
Actual (Non-Junction) Qtree Path: /vol/data1/qt01
 Security Style: unix
 Oblock Mode: enable
 Unix Permissions: ---rwxr-xr-x
 Qtree Id: 2
 Qtree Status: normal
 Export Policy: default
Is Export Policy Inherited: true

```

## Secure NFS access using export policies

### Secure NFS access using export policies

You can use export policies to restrict NFS access to volumes or qtrees to clients that match specific parameters. When provisioning new storage, you can use an existing policy and rules, add rules to an existing policy, or create a new policy and rules. You can also check the configuration of export policies

 Beginning with ONTAP 9.3, you can enable export policy configuration checking as a background job that records any rules violations in an error rule list. The `vserver export-policy config-checker` commands invoke the checker and display results, which you can use to verify your configuration and delete erroneous rules from the policy. The commands only validate export configuration for host names, netgroups, and anonymous users.

### Manage the processing order of export rules

You can use the `vserver export-policy rule setindex` command to manually set an existing export rule's index number. This enables you to specify the precedence by which ONTAP applies export rules to client requests.

#### About this task

If the new index number is already in use, the command inserts the rule at the specified spot and reorders the list accordingly.

#### Step

1. Modify the index number of a specified export rule:

```
vserver export-policy rule setindex -vserver virtual_server_name -policyname policy_name -ruleindex integer -newruleindex integer
```

## Example

The following command changes the index number of an export rule at index number 3 to index number 2 in an export policy named rs1 on the SVM named vs1:

```
vs1::> vserver export-policy rule setindex -vserver vs1 -policyname rs1 -ruleindex 3 -newruleindex 2
```

## Assign an export policy to a volume

Each volume contained in the SVM must be associated with an export policy that contains export rules for clients to access data in the volume.

### About this task

You can associate an export policy to a volume when you create the volume or at any time after you create the volume. You can associate one export policy to the volume, although one policy can be associated to many volumes.

### Steps

1. If an export policy was not specified when the volume was created, assign an export policy to the volume:

```
volume modify -vserver vserver_name -volume volume_name -policy export_policy_name
```

2. Verify that the policy was assigned to the volume:

```
volume show -volume volume_name -fields policy
```

## Example

The following commands assign the export policy nfs\_policy to the volume vol1 on the SVM vs1 and verify the assignment:

```
cluster::> volume modify -vserver vs1 -volume vol1 -policy nfs_policy

cluster::>volume show -volume vol -fields policy
vserver volume policy

vs1 vol1 nfs_policy
```

## Assign an export policy to a qtree

Instead of exporting an entire volume, you can also export a specific qtree on a volume to make it directly accessible to clients. You can export a qtree by assigning an export policy to it. You can assign the export policy either when you create a new qtree or by modifying an existing qtree.

## What you'll need

The export policy must exist.

## About this task

By default, qtrees inherit the parent export policy of the containing volume if not otherwise specified at the time of creation.

You can associate an export policy to a qtree when you create the qtree or at any time after you create the qtree. You can associate one export policy to the qtree, although one policy can be associated with many qtrees.

## Steps

1. If an export policy was not specified when the qtree was created, assign an export policy to the qtree:

```
volume qtree modify -vserver vserver_name -qtree-path
/vol/volume_name/qtree_name -export-policy export_policy_name
```

2. Verify that the policy was assigned to the qtree:

```
volume qtree show -qtree qtree_name -fields export-policy
```

## Example

The following commands assign the export policy nfs\_policy to the qtree qt1 on the SVM vs1 and verify the assignment:

```
cluster::> volume modify -v1server vs1 -qtree-path /vol/vol1/qt1 -policy
nfs_policy

cluster::>volume qtree show -volume vol1 -fields export-policy
vserver volume qtree export-policy

vs1 data1 qt01 nfs_policy
```

## Verify NFS client access from the cluster

You can give select clients access to the share by setting UNIX file permissions on a UNIX administration host. You can check client access by using the vserver export-policy check-access command, adjusting the export rules as necessary.

## Steps

1. On the cluster, check client access to exports by using the vserver export-policy check-access command.

The following command checks read/write access for an NFSv3 client with the IP address 1.2.3.4 to the volume home2. The command output shows that the volume uses the export policy exp-home-dir and that access is denied.

```

cluster1::> vserver export-policy check-access -vserver vs1 -client-ip
1.2.3.4 -volume home2 -authentication-method sys -protocol nfs3 -access
-type read-write

```

| Path       | Policy       | Owner    | Policy Owner | Rule Type | Index | Access |
|------------|--------------|----------|--------------|-----------|-------|--------|
| /          | default      | vs1_root | volume       |           | 1     | read   |
| /eng       | default      | vs1_root | volume       |           | 1     | read   |
| /eng/home2 | exp-home-dir | home2    | volume       |           | 1     | denied |

3 entries were displayed.

- Examine the output to determine whether the export policy works as intended and the client access behaves as expected.

Specifically, you should verify which export policy is used by the volume or qtree and the type of access the client has as a result.

- If necessary, reconfigure the export policy rules.

### Test NFS access from client systems

After you verify NFS access to the new storage object, you should test the configuration by logging in to an NFS administration host and reading data from and writing data to the SVM. You should then repeat the process as a non-root user on a client system.

#### What you'll need

- The client system must have an IP address that is allowed by the export rule you specified earlier.
- You must have the login information for the root user.

#### Steps

- On the cluster, verify the IP address of the LIF that is hosting the new volume:

```
network interface show -vserver svm_name
```

- Log in as the root user to the administration host client system.
- Change the directory to the mount folder:

```
cd /mnt/
```

- Create and mount a new folder using the IP address of the SVM:

- Create a new folder:

```
mkdir /mnt/folder
```

- Mount the new volume at this new directory:

```
mount -t nfs -o hard IPAddress:/volume_name /mnt/folder
```

- c. Change the directory to the new folder:

```
cd folder
```

The following commands create a folder named test1, mount the vol1 volume at the 192.0.2.130 IP address on the test1 mount folder, and change to the new test1 directory:

```
host# mkdir /mnt/test1
host# mount -t nfs -o hard 192.0.2.130:/vol1 /mnt/test1
host# cd /mnt/test1
```

5. Create a new file, verify that it exists, and write text to it:

- a. Create a test file:

```
touch filename
```

- b. Verify that the file exists.:

```
ls -l filename
```

- c. Enter:

```
cat > filename
```

Type some text, and then press Ctrl+D to write text to the test file.

- d. Display the content of the test file.

```
cat filename
```

- e. Remove the test file:

```
rm filename
```

- f. Return to the parent directory:

```
cd ..
```

```
host# touch myfile1
host# ls -l myfile1
-rw-r--r-- 1 root root 0 Sep 18 15:58 myfile1
host# cat >myfile1
This text inside the first file
host# cat myfile1
This text inside the first file
host# rm -r myfile1
host# cd ..
```

6. As root, set any desired UNIX ownership and permissions on the mounted volume.
7. On a UNIX client system identified in your export rules, log in as one of the authorized users who now has access to the new volume, and repeat the procedures in steps 3 to 5 to verify that you can mount the volume and create a file.

## Where to find additional information

After you have successfully tested NFS client access, you can perform additional NFS configuration or add SAN access. When protocol access is complete, you should protect the root volume of storage virtual machine (SVM).

### NFS configuration

You can further configure NFS access using the following information and technical reports:

- [NFS management](#)

Describes how to configure and manage file access using NFS.

- [NetApp Technical Report 4067: NFS Best Practice and Implementation Guide](#)

Serves as an NFSv3 and NFSv4 operational guide, and provides an overview of the ONTAP operating system with a focus on NFSv4.

- [NetApp Technical Report 4073: Secure Unified Authentication](#)

Explains how to configure ONTAP for use with UNIX-based Kerberos version 5 (krb5) servers for NFS storage authentication and Windows Server Active Directory (AD) as the KDC and Lightweight Directory Access Protocol (LDAP) identity provider.

- [NetApp Technical Report 3580: NFSv4 Enhancements and Best Practices Guide Data ONTAP Implementation](#)

Describes the best practices that should be followed while implementing NFSv4 components on AIX, Linux, or Solaris clients attached to systems running ONTAP.

### Networking configuration

You can further configure networking features and name services using the following information and technical reports:

- [NFS management](#)

Describes how to configure and manage ONTAP networking.

- [NetApp Technical Report 4182: Ethernet Storage Design Considerations and Best Practices for Clustered Data ONTAP Configurations](#)

Describes the implementation of ONTAP network configurations, and provides common network deployment scenarios and best practice recommendations.

- [NetApp Technical Report 4668: Name Services Best Practices Guide](#)

Explains how to configure LDAP, NIS, DNS, and local file configuration for authentication purposes.

## SAN protocol configuration

If you want to provide or modify SAN access to the new SVM, you can use the FC or iSCSI configuration information, which is available for multiple host operating systems.

## Root volume protection

After configuring protocols on the SVM, you should ensure that its root volume is protected:

- [Data protection](#)

Describes how to create a load-sharing mirror to protect the SVM root volume, which is a NetApp best practice for NAS-enabled SVMs. Also describes how to quickly recover from volume failures or losses by promoting the SVM root volume from a load-sharing mirror.

## How ONTAP exports differ from 7-Mode exports

### How ONTAP exports differ from 7-Mode exports

If you are unfamiliar with how ONTAP implements NFS exports, you can compare 7-Mode and ONTAP export configuration tools, as well as sample 7-Mode /etc/exports files with clustered policies and rules.

In ONTAP there is no /etc/exports file and no exportfs command. Instead, you must define an export policy. Export policies enable you to control client access in much the same way as you did in 7-Mode, but give you additional functionality such as the ability to reuse the same export policy for multiple volumes.

### Related information

### Comparison of exports in 7-Mode and ONTAP

Exports in ONTAP are defined and used differently than they are in 7-Mode environments.

| Areas of difference     | 7-Mode                                        | ONTAP                                                                                                           |
|-------------------------|-----------------------------------------------|-----------------------------------------------------------------------------------------------------------------|
| How exports are defined | Exports are defined in the /etc/exports file. | Exports are defined by creating an export policy within an SVM. An SVM can include more than one export policy. |

|                                                                                  |                                                                                                                                                                                                                                                                                                        |                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
|----------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Scope of export                                                                  | <ul style="list-style-type: none"> <li>Exports apply to a specified file path or qtree.</li> <li>You must create a separate entry in <code>/etc/exports</code> for each file path or qtree.</li> <li>Exports are persistent only if they are defined in the <code>/etc/exports</code> file.</li> </ul> | <ul style="list-style-type: none"> <li>Export policies apply to an entire volume, including all of the file paths and qtrees contained in the volume.</li> <li>Export policies can be applied to more than one volume if you want.</li> <li>All export policies are persistent across system restarts.</li> </ul>                                                                                                                                             |
| Fencing (specifying different access for specific clients to the same resources) | To provide specific clients different access to a single exported resource, you have to list each client and its permitted access in the <code>/etc/exports</code> file.                                                                                                                               | Export policies are composed of a number of individual export rules. Each export rule defines specific access permissions for a resource and lists the clients that have those permissions. To specify different access for specific clients, you have to create an export rule for each specific set of access permissions, list the clients that have those permissions, and then add the rules to the export policy.                                       |
| Name aliasing                                                                    | When you define an export, you can choose to make the name of the export different from the name of the file path. You should use the <code>-actual</code> parameter when defining such an export in the <code>/etc/exports</code> file.                                                               | <p>You can choose to make the name of the exported volume different from the actual volume name. To do this, you must mount the volume with a custom junction path name within the SVM namespace.</p> <p> By default, volumes are mounted with their volume name. To customize a volume's junction path name you need to unmount it, rename it, and then remount it.</p> |

## Examples of ONTAP export policies

You can review example export policies to better understand how export policies work in ONTAP.

### Sample ONTAP implementation of a 7-Mode export

The following example shows a 7-Mode export as it appears in the `/etc/export` file:

```
/vol/vol1 -sec=sys,ro=@readonly_netgroup,rw=@readwrite_netgroup1:
@readwrite_netgroup2:@rootaccess_netgroup,root=@rootaccess_netgroup
```

To reproduce this export as a clustered export policy, you have to create an export policy with three export rules, and then assign the export policy to the volume vol1.

| Rule   | Element                                                  | Value                                    |
|--------|----------------------------------------------------------|------------------------------------------|
| Rule 1 | -clientmatch (client specification)                      | @readonly_netgroup                       |
|        | -ruleindex(position of export rule in the list of rules) | 1                                        |
|        | -protocol                                                | nfs                                      |
|        | -rorule(allow read-only access)                          | sys (client authenticated with AUTH_SYS) |
|        | -rwrule(allow read-write access)                         | never                                    |
|        | -superuser(allow superuser access)                       | none(root <i>squashed</i> to anon)       |
| Rule 2 | -clientmatch                                             | @rootaccess_netgroup                     |
|        | -ruleindex                                               | 2                                        |
|        | -protocol                                                | nfs                                      |
|        | -rorule                                                  | sys                                      |
|        | -rwrule                                                  | sys                                      |
|        | -superuser                                               | sys                                      |

| Rule   | Element      | Value                                     |
|--------|--------------|-------------------------------------------|
| Rule 3 | -clientmatch | @readwrite_netgroup1,@readwrite_netgroup2 |
|        | -ruleindex   | 3                                         |
|        | -protocol    | nfs                                       |
|        | -rorule      | sys                                       |
|        | -rwrule      | sys                                       |
|        | -superuser   | none                                      |

1. Create an export policy called exp\_vol1:

```
vserver export-policy create -vserver NewSVM -policyname exp_vol1
```

2. Create three rules with the following parameters to the base command:

- Base command:

```
vserver export-policy rule create -vserver NewSVM -policyname exp_vol1
```

- Rule parameters:

```
-clientmatch @readonly_netgroup -ruleindex 1 -protocol nfs -rorule sys
-rwrule never -superuser none
```

```
-clientmatch @rootaccess_netgroup -ruleindex 2 -protocol nfs -rorule sys
-rwrule sys -superuser sys
```

```
-clientmatch @readwrite_netgroup1,@readwrite_netgroup2 -ruleindex 3
-protocol nfs -rorule sys -rwrule sys -superuser none
```

3. Assign the policy to the volume vol1:

```
volume modify -vserver NewSVM -volume vol1 -policy exp_vol1
```

#### Sample consolidation of 7-Mode exports

The following example shows a 7-Mode /etc/export file that includes one line for each of 10 qtrees:

```
/vol/vol1/q_1472 -sec=sys,rw=host1519s,root=host1519s
/vol/vol1/q_1471 -sec=sys,rw=host1519s,root=host1519s
/vol/vol1/q_1473 -sec=sys,rw=host1519s,root=host1519s
/vol/vol1/q_1570 -sec=sys,rw=host1519s,root=host1519s
/vol/vol1/q_1571 -sec=sys,rw=host1519s,root=host1519s
/vol/vol1/q_2237 -sec=sys,rw=host2057s,root=host2057s
/vol/vol1/q_2238 -sec=sys,rw=host2057s,root=host2057s
/vol/vol1/q_2239 -sec=sys,rw=host2057s,root=host2057s
/vol/vol1/q_2240 -sec=sys,rw=host2057s,root=host2057s
/vol/vol1/q_2241 -sec=sys,rw=host2057s,root=host2057s
```

In ONTAP, one of two policies is needed for each qtree: one with a rule including `-clientmatch host1519s`, or one with a rule including `-clientmatch host2057s`.

1. Create two export policies called `exp_vol1q1` and `exp_vol1q2`:

- `vserver export-policy create -vserver NewSVM -policyname exp_vol1q1`
- `vserver export-policy create -vserver NewSVM -policyname exp_vol1q2`

2. Create a rule for each policy:

- `vserver export-policy rule create -vserver NewSVM -policyname exp_vol1q1 -clientmatch host1519s -rwrule sys -superuser sys`
- `vserver export-policy rule create -vserver NewSVM -policyname exp_vol1q2 -clientmatch host1519s -rwrule sys -superuser sys`

3. Apply the policies to the qtrees:

- `volume qtree modify -vserver NewSVM -qtree-path /vol/vol1/q_1472 -export -policy exp_vol1q1`
- [next 4 qtrees...]
- `volume qtree modify -vserver NewSVM -qtree-path /vol/vol1/q_2237 -export -policy exp_vol1q2`
- [next 4 qtrees...]

If you need to add additional qtrees for those hosts later, you would use the same export policies.

## Manage NFS with the CLI

### NFS reference overview

ONTAP includes file access features available for the NFS protocol. You can enable an NFS server and export volumes or qtrees.

You perform these procedure under the following circumstances:

- You want to understand the range of ONTAP NFS protocol capabilities.
- You want to perform less common configuration and maintenance tasks, not basic NFS configuration.

- You want to use the command-line interface (CLI), not System Manager or an automated scripting tool.

## Understand NAS file access

### Namespaces and junction points

#### Namespaces and junction points overview

A NAS *namespace* is a logical grouping of volumes joined together at *junction points* to create a single file system hierarchy. A client with sufficient permissions can access files in the namespace without specifying the location of the files in storage. Junctioned volumes can reside anywhere in the cluster.

Rather than mounting every volume containing a file of interest, NAS clients mount an NFS *export* or access an SMB *share*. The export or share represents the entire namespace or an intermediate location within the namespace. The client accesses only the volumes mounted below its access point.

You can add volumes to the namespace as needed. You can create junction points directly below a parent volume junction or on a directory within a volume. A path to a volume junction for a volume named “vol3” might be /vol1/vol2/vol3, or /vol1/dir2/vol3, or even /dir1/dir2/vol3. The path is called the *junction path*.

Every SVM has a unique namespace. The SVM root volume is the entry point to the namespace hierarchy.

To ensure that data remains available in the event of a node outage or failover, you should create a *load-sharing mirror* copy for the SVM root volume.

*A namespace is a logical grouping of volumes joined together at junction points to create a single file system hierarchy.*

#### Example

The following example creates a volume named “home4” located on SVM vs1 that has a junction path /eng/home:

```
cluster1::> volume create -vserver vs1 -volume home4 -aggregate aggr1
-size 1g -junction-path /eng/home
[Job 1642] Job succeeded: Successful
```

#### What the typical NAS namespace architectures are

There are several typical NAS namespace architectures that you can use as you create your SVM name space. You can choose the namespace architecture that matches your business and workflow needs.

The top of the namespace is always the root volume, which is represented by a slash (/). The namespace architecture under the root falls into three basic categories:

- A single branched tree, with only a single junction to the root of the namespace

- Multiple branched trees, with multiple junction points to the root of the namespace
- Multiple stand-alone volumes, each with a separate junction point to the root of the name space

### Namespace with single branched tree

An architecture with a single branched tree has a single insertion point to the root of the SVM namespace. The single insertion point can be either a junctioned volume or a directory beneath the root. All other volumes are mounted at junction points beneath the single insertion point (which can be a volume or a directory).

For example, a typical volume junction configuration with the above namespace architecture might look like the following configuration, where all volumes are junctioned below the single insertion point, which is a directory named “data”:

| Vserver | Volume   | Junction Active | Junction Path     | Junction Path Source |
|---------|----------|-----------------|-------------------|----------------------|
| vs1     | corp1    | true            | /data/dir1/corp1  | RW_volume            |
| vs1     | corp2    | true            | /data/dir1/corp2  | RW_volume            |
| vs1     | data1    | true            | /data/data1       | RW_volume            |
| vs1     | eng1     | true            | /data/data1/eng1  | RW_volume            |
| vs1     | eng2     | true            | /data/data1/eng2  | RW_volume            |
| vs1     | sales    | true            | /data/data1/sales | RW_volume            |
| vs1     | vol1     | true            | /data/vol1        | RW_volume            |
| vs1     | vol2     | true            | /data/vol2        | RW_volume            |
| vs1     | vol3     | true            | /data/vol3        | RW_volume            |
| vs1     | vs1_root | -               | /                 | -                    |

## Namespace with multiple branched trees

An architecture with multiple branched trees has multiple insertion points to the root of the SVM namespace. The insertion points can be either junctioned volumes or directories beneath the root. All other volumes are mounted at junction points beneath the insertion points (which can be volumes or directories).

For example, a typical volume junction configuration with the above namespace architecture might look like the following configuration, where there are three insertion points to the root volume of the SVM. Two insertion points are directories named "data" and "projects". One insertion point is a junctioned volume named "audit":

| Vserver | Volume      | Junction |                    |      | Junction Path Source |
|---------|-------------|----------|--------------------|------|----------------------|
|         |             | Active   | Junction           | Path |                      |
| vs1     | audit       | true     | /audit             |      | RW_volume            |
| vs1     | audit_logs1 | true     | /audit/logs1       |      | RW_volume            |
| vs1     | audit_logs2 | true     | /audit/logs2       |      | RW_volume            |
| vs1     | audit_logs3 | true     | /audit/logs3       |      | RW_volume            |
| vs1     | eng         | true     | /data/eng          |      | RW_volume            |
| vs1     | mktg1       | true     | /data/mktg1        |      | RW_volume            |
| vs1     | mktg2       | true     | /data/mktg2        |      | RW_volume            |
| vs1     | project1    | true     | /projects/project1 |      | RW_volume            |
| vs1     | project2    | true     | /projects/project2 |      | RW_volume            |
| vs1     | vs1_root    | -        | /                  |      | -                    |

## Namespace with multiple stand-alone volumes

In an architecture with stand-alone volumes, every volume has an insertion point to the root of the SVM namespace; however, the volume is not junctioned below another volume. Each volume has a unique path,

and is either junctioned directly below the root or is junctioned under a directory below the root.

For example, a typical volume junction configuration with the above namespace architecture might look like the following configuration, where there are five insertion points to the root volume of the SVM, with each insertion point representing a path to one volume.

| Vserver | Volume   | Junction |           |      | Junction Path Source |
|---------|----------|----------|-----------|------|----------------------|
|         |          | Active   | Junction  | Path |                      |
| vs1     | eng      | true     | /eng      |      | RW_volume            |
| vs1     | mktg     | true     | /vol/mktg |      | RW_volume            |
| vs1     | project1 | true     | /project1 |      | RW_volume            |
| vs1     | project2 | true     | /project2 |      | RW_volume            |
| vs1     | sales    | true     | /sales    |      | RW_volume            |
| vs1     | vs1_root | -        | /         |      | -                    |

## How ONTAP controls access to files

### How ONTAP controls access to files overview

ONTAP controls access to files according to the authentication-based and file-based restrictions that you specify.

When a client connects to the storage system to access files, ONTAP has to perform two tasks:

- Authentication

ONTAP has to authenticate the client by verifying the identity with a trusted source. In addition, the

authentication type of the client is one method that can be used to determine whether a client can access data when configuring export policies (optional for CIFS).

- Authorization

ONTAP has to authorize the user by comparing the user's credentials with the permissions configured on the file or directory and determining what type of access, if any, to provide.

To properly manage file access control, ONTAP must communicate with external services such as NIS, LDAP, and Active Directory servers. Configuring a storage system for file access using CIFS or NFS requires setting up the appropriate services depending on your environment in ONTAP.

#### **Authentication-based restrictions**

With authentication-based restrictions, you can specify which client machines and which users can connect to the storage virtual machine (SVM).

ONTAP supports Kerberos authentication from both UNIX and Windows servers.

#### **File-based restrictions**

ONTAP evaluates three levels of security to determine whether an entity is authorized to perform a requested action on files and directories residing on an SVM. Access is determined by the effective permissions after evaluation of the three security levels.

Any storage object can contain up to three types of security layers:

- Export (NFS) and share (SMB) security

Export and share security applies to client access to a given NFS export or SMB share. Users with administrative privileges can manage export and share-level security from SMB and NFS clients.

- Storage-Level Access Guard file and directory security

Storage-Level Access Guard security applies to SMB and NFS client access to SVM volumes. Only NTFS access permissions are supported. For ONTAP to perform security checks on UNIX users for access to data on volumes for which Storage-Level Access Guard has been applied, the UNIX user must map to a Windows user on the SVM that owns the volume.

If you view the security settings on a file or directory from an NFS or SMB client, you will not see Storage-Level Access Guard security. Storage-Level Access Guard security cannot be revoked from a client, even by a system (Windows or UNIX) administrator.

- NTFS, UNIX, and NFSv4 native file-level security

Native file-level security exists on the file or directory that represents the storage object. You can set file-level security from a client. File permissions are effective regardless of whether SMB or NFS is used to access the data.

#### **How ONTAP handles NFS client authentication**

## How ONTAP handles NFS client authentication overview

NFS clients must be properly authenticated before they can access data on the SVM. ONTAP authenticates the clients by checking their UNIX credentials against the name services that you configure.

When an NFS client connects to the SVM, ONTAP obtains the UNIX credentials for the user by checking different name services, depending on the name services configuration of the SVM. ONTAP can check credentials for local UNIX accounts, NIS domains, and LDAP domains. At least one of them must be configured so that ONTAP can successfully authenticate the user. You can specify multiple name services and the order in which ONTAP searches them.

In a pure NFS environment with UNIX volume security styles, this configuration is sufficient to authenticate and provide the proper file access for a user connecting from an NFS client.

If you are using mixed, NTFS, or unified volume security styles, ONTAP must obtain a SMB user name for the UNIX user for authentication with a Windows domain controller. This can happen either by mapping individual users using local UNIX accounts or LDAP domains, or by using a default SMB user instead. You can specify which name services ONTAP searches in which order, or specify a default SMB user.

## How ONTAP uses name services

ONTAP uses name services to obtain information about users and clients. ONTAP uses this information to authenticate users accessing data on or administering the storage system, and to map user credentials in a mixed environment.

When you configure the storage system, you must specify what name services you want ONTAP to use for obtaining user credentials for authentication. ONTAP supports the following name services:

- Local users (file)
- External NIS domains (NIS)
- External LDAP domains (LDAP)

You use the `vserver services name-service ns-switch` command family to configure SVMs with the sources to search for network information and the order in which to search them. These commands provide the equivalent functionality of the `/etc/nsswitch.conf` file on UNIX systems.

When an NFS client connects to the SVM, ONTAP checks the specified name services to obtain the UNIX credentials for the user. If name services are configured correctly and ONTAP can obtain the UNIX credentials, ONTAP successfully authenticates the user.

In an environment with mixed security styles, ONTAP might have to map user credentials. You must configure name services appropriately for your environment to allow ONTAP to properly map user credentials.

ONTAP also uses name services for authenticating SVM administrator accounts. You must keep this in mind when configuring or modifying the name service switch to avoid accidentally disabling authentication for SVM administrator accounts. For more information about SVM administration users, see [Administrator authentication and RBAC](#).

## How ONTAP grants SMB file access from NFS clients

ONTAP uses Windows NT File System (NTFS) security semantics to determine whether a UNIX user, on an NFS client, has access to a file with NTFS permissions.

ONTAP does this by converting the user's UNIX User ID (UID) into a SMB credential, and then using the SMB credential to verify that the user has access rights to the file. A SMB credential consists of a primary Security Identifier (SID), usually the user's Windows user name, and one or more group SIDs that correspond to Windows groups of which the user is a member.

The time ONTAP takes converting the UNIX UID into a SMB credential can be from tens of milliseconds to hundreds of milliseconds because the process involves contacting a domain controller. ONTAP maps the UID to the SMB credential and enters the mapping in a credential cache to reduce the verification time caused by the conversion.

#### How the NFS credential cache works

When an NFS user requests access to NFS exports on the storage system, ONTAP must retrieve the user credentials either from external name servers or from local files to authenticate the user. ONTAP then stores these credentials in an internal credential cache for later reference. Understanding how the NFS credential caches works enables you to handle potential performance and access issues.

Without the credential cache, ONTAP would have to query name services every time an NFS user requested access. On a busy storage system that is accessed by many users, this can quickly lead to serious performance problems, causing unwanted delays or even denials to NFS client access.

With the credential cache, ONTAP retrieves the user credentials and then stores them for a predetermined amount of time for quick and easy access should the NFS client send another request. This method offers the following advantages:

- It eases the load on the storage system by handling fewer requests to external name servers (such as NIS or LDAP).
- It eases the load on external name servers by sending fewer requests to them.
- It speeds up user access by eliminating the wait time for obtaining credentials from external sources before the user can be authenticated.

ONTAP stores both positive and negative credentials in the credential cache. Positive credentials means that the user was authenticated and granted access. Negative credentials means that the user was not authenticated and was denied access.

By default, ONTAP stores positive credentials for 24 hours; that is, after initially authenticating a user, ONTAP uses the cached credentials for any access requests by that user for 24 hours. If the user requests access after 24 hours, the cycle starts over: ONTAP discards the cached credentials and obtains the credentials again from the appropriate name service source. If the credentials changed on the name server during the previous 24 hours, ONTAP caches the updated credentials for use for the next 24 hours.

By default, ONTAP stores negative credentials for two hours; that is, after initially denying access to a user, ONTAP continues to deny any access requests by that user for two hours. If the user requests access after 2 hours, the cycle starts over: ONTAP obtains the credentials again from the appropriate name service source. If the credentials changed on the name server during the previous two hours, ONTAP caches the updated credentials for use for the next two hours.

## Create and manage data volumes in NAS namespaces

## Create data volumes with specified junction points

You can specify the junction point when you create a data volume. The resultant volume is automatically mounted at the junction point and is immediately available to configure for NAS access.

### Before you begin

- The aggregate in which you want to create the volume must already exist.
- Beginning in ONTAP 9.13.1, you can create volumes with capacity analytics and Activity Tracking enabled. To enable capacity or Activity Tracking, issue the `volume create` command with `-analytics-state` or `-activity-tracking-state` set to on.

To learn more about capacity analytics and Activity Tracking, see [Enable File System Analytics](#).

The following characters cannot be used in the junction path: \* # " > < | ? \

+

In addition, the junction path length cannot be more than 255 characters.

### Steps

1. Create the volume with a junction point:

```
volume create -vserver vserver_name -volume volume_name -aggregate
aggregate_name -size {integer[KB|MB|GB|TB|PB]} -security-style
{ntfs|unix|mixed} -junction-path junction_path
```

The junction path must start with the root (/) and can contain both directories and junctioned volumes. The junction path does not need to contain the name of the volume. Junction paths are independent of the volume name.

Specifying a volume security style is optional. If you do not specify a security style, ONTAP creates the volume with the same security style that is applied to the root volume of the storage virtual machine (SVM). However, the root volume's security style might not be the security style you want applied to the data volume you create. The recommendation is to specify the security style when you create the volume to minimize difficult-to-troubleshoot file-access issues.

The junction path is case insensitive; /ENG is the same as /eng. If you create a CIFS share, Windows treats the junction path as if it is case sensitive. For example, if the junction is /ENG, the path of a SMB share must start with /ENG, not /eng.

There are many optional parameters that you can use to customize a data volume. To learn more about them, see the man pages for the `volume create` command.

2. Verify that the volume was created with the desired junction point:

```
volume show -vserver vserver_name -volume volume_name -junction
```

### Example

The following example creates a volume named "home4" located on SVM vs1 that has a junction path /eng/home:

```

cluster1::> volume create -vserver vs1 -volume home4 -aggregate aggr1
-size 1g -junction-path /eng/home
[Job 1642] Job succeeded: Successful

cluster1::> volume show -vserver vs1 -volume home4 -junction
 Junction Junction
 Vserver Volume Active Junction Path Path Source
----- -----
vs1 home4 true /eng/home RW_volume

```

### Create data volumes without specifying junction points

You can create a data volume without specifying a junction point. The resultant volume is not automatically mounted, and is not available to configure for NAS access. You must mount the volume before you can configure SMB shares or NFS exports for that volume.

#### Before you begin

- The aggregate in which you want to create the volume must already exist.
- Beginning in ONTAP 9.13.1, you can create volumes with capacity analytics and Activity Tracking enabled. To enable capacity or Activity Tracking, issue the `volume create` command with `-analytics-state` or `-activity-tracking-state` set to on.

To learn more about capacity analytics and Activity Tracking, see [Enable File System Analytics](#).

#### Steps

- Create the volume without a junction point by using the following command:

```

volume create -vserver vserver_name -volume volume_name -aggregate
aggregate_name -size {integer[KB|MB|GB|TB|PB]} -security-style
{ntfs|unix|mixed}

```

Specifying a volume security style is optional. If you do not specify a security style, ONTAP creates the volume with the same security style that is applied to the root volume of the storage virtual machine (SVM). However, the root volume's security style might not be the security style you want applied to the data volume. The recommendation is to specify the security style when you create the volume to minimize difficult-to-troubleshoot file-access issues.

There are many optional parameters that you can use to customize a data volume. To learn more about them, see the man pages for the `volume create` command.

- Verify that the volume was created without a junction point:

```

volume show -vserver vserver_name -volume volume_name -junction

```

#### Example

The following example creates a volume named "sales" located on SVM vs1 that is not mounted at a junction point:

```
cluster1::> volume create -vserver vs1 -volume sales -aggregate aggr3
-size 20GB
[Job 3406] Job succeeded: Successful
```

| Vserver | Volume   | Junction |               | Junction  |        |
|---------|----------|----------|---------------|-----------|--------|
|         |          | Active   | Junction Path | Path      | Source |
| vs1     | data     | true     | /data         | RW_volume |        |
| vs1     | home4    | true     | /eng/home     | RW_volume |        |
| vs1     | vs1_root | -        | /             | -         |        |
| vs1     | sales    | -        | -             | -         |        |

## Mount or unmount existing volumes in the NAS namespace

A volume must be mounted on the NAS namespace before you can configure NAS client access to data contained in the storage virtual machine (SVM) volumes. You can mount a volume to a junction point if it is not currently mounted. You can also unmount volumes.

### About this task

If you unmount and offline a volume, all data within the junction point, including data in volumes with junction points contained within the unmounted volume's namespace, are inaccessible to NAS clients.

 To discontinue NAS client access to a volume, it is not sufficient to simply unmount the volume. You must offline the volume, or take other steps to ensure that client-side file handle caches are invalidated. For more information, see the following Knowledge Base article:

[NFSv3 clients still have access to a volume after being removed from the namespace in ONTAP](#)

When you unmount and offline a volume, data within the volume is not lost. Additionally, existing volume export policies and SMB shares created on the volume or on directories and junction points within the unmounted volume are retained. If you remount the unmounted volume, NAS clients can access the data contained within the volume using existing export policies and SMB shares.

### Steps

1. Perform the desired action:

| If you want to... | Enter the commands...                                                                                        |
|-------------------|--------------------------------------------------------------------------------------------------------------|
| Mount a volume    | volume mount -vserver svm_name -volume volume_name -junction-path junction_path                              |
| Unmount a volume  | volume unmount -vserver svm_name -volume volume_name volume offline<br>-vserver svm_name -volume volume_name |

**2. Verify that the volume is in the desired mount state:**

```
volume show -vserver vserver_name -volume volume_name -fields state,junction-path,junction-active
```

**Examples**

The following example mounts a volume named “sales” located on SVM vs1 to the junction point /sales:

```
cluster1::> volume mount -vserver vs1 -volume sales -junction-path /sales

cluster1::> volume show -vserver vs1 state,junction-path,junction-active

vserver volume state junction-path junction-active
----- ----- -----
vs1 data online /data true
vs1 home4 online /eng/home true
vs1 sales online /sales true
```

The following example unmounts and offline a volume named “data” located on SVM vs1:

```
cluster1::> volume unmount -vserver vs1 -volume data
cluster1::> volume offline -vserver vs1 -volume data

cluster1::> volume show -vserver vs1 -fields state,junction-path,junction-active

vserver volume state junction-path junction-active
----- ----- -----
vs1 data offline - -
vs1 home4 online /eng/home true
vs1 sales online /sales true
```

**Display volume mount and junction point information**

You can display information about mounted volumes for storage virtual machines (SVMs) and the junction points to which the volumes are mounted. You can also determine which volumes are not mounted to a junction point. You can use this information to understand and manage your SVM namespace.

**Step**

1. Perform the desired action:

|                           |                      |
|---------------------------|----------------------|
| If you want to display... | Enter the command... |
|---------------------------|----------------------|

|                                                                     |                                                                                                                                                                                                                                                                                                                                      |
|---------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Summary information about mounted and unmounted volumes on the SVM  | <code>volume show -vserver vserver_name -junction</code>                                                                                                                                                                                                                                                                             |
| Detailed information about mounted and unmounted volumes on the SVM | <code>volume show -vserver vserver_name -volume volume_name -instance</code>                                                                                                                                                                                                                                                         |
| Specific information about mounted and unmounted volumes on the SVM | <p>a. If necessary, you can display valid fields for the <code>-fields</code> parameter by using the following command:<br/> <code>volume show -fields ?</code></p> <p>b. Display the desired information by using the <code>-fields</code> parameter:<br/> <code>volume show -vserver vserver_name -fields fieldname,...</code></p> |

## Examples

The following example displays a summary of mounted and unmounted volumes on SVM vs1:

```
cluster1::> volume show -vserver vs1 -junction
 Junction Junction
Vserver Volume Active Junction Path Path Source
----- -----
vs1 data true /data RW_volume
vs1 home4 true /eng/home RW_volume
vs1 vs1_root - / -
vs1 sales true /sales RW_volume
```

The following example displays information about specified fields for volumes located on SVM vs2:

```

cluster1::> volume show -vserver vs2 -fields
vserver,volume,aggregate,size,state,type,security-style,junction-
path,junction-parent,node
vserver volume aggregate size state type security-style junction-path
junction-parent node

vs2 data1 aggr3 2GB online RW unix -
node3
vs2 data2 aggr3 1GB online RW ntfs /data2
vs2_root node3
vs2 data2_1 aggr3 8GB online RW ntfs /data2/d2_1
data2 node3
vs2 data2_2 aggr3 8GB online RW ntfs /data2/d2_2

```

## Configure security styles

### How security styles affect data access

#### What the security styles and their effects are

There are four different security styles: UNIX, NTFS, mixed, and unified. Each security style has a different effect on how permissions are handled for data. You must understand the different effects to ensure that you select the appropriate security style for your purposes.

It is important to understand that security styles do not determine what client types can or cannot access data. Security styles only determine the type of permissions ONTAP uses to control data access and what client type can modify these permissions.

For example, if a volume uses UNIX security style, SMB clients can still access data (provided that they properly authenticate and authorize) due to the multiprotocol nature of ONTAP. However, ONTAP uses UNIX permissions that only UNIX clients can modify using native tools.

| Security style                                                             | Clients that can modify permissions | Permissions that clients can use | Resulting effective security style | Clients that can access files |
|----------------------------------------------------------------------------|-------------------------------------|----------------------------------|------------------------------------|-------------------------------|
| Unix                                                                       | NFS                                 | NFSv3 mode bits                  | Unix                               | NFS and SMB                   |
|                                                                            |                                     | NFSv4.x ACLs                     |                                    |                               |
| NTFS                                                                       | SMB                                 | NTFS ACLs                        | NTFS                               |                               |
| Mixed                                                                      | NFS or SMB                          | NFSv3 mode bits                  | UNIX                               |                               |
|                                                                            |                                     | NFSv4.ACLs                       |                                    |                               |
|                                                                            |                                     | NTFS ACLs                        | NTFS                               |                               |
| Unified<br>(For infinite volumes only, in ONTAP 9.4 and earlier releases.) | NFS or SMB                          | NFSv3 mode bits                  | Unix                               |                               |
|                                                                            |                                     | NFSv4.1 ACLs                     |                                    |                               |
|                                                                            |                                     | NTFS ACLs                        | NTFS                               |                               |

FlexVol volumes support UNIX, NTFS, and mixed security styles. When the security style is mixed or unified, the effective permissions depend on the client type that last modified the permissions because users set the security style on an individual basis. If the last client that modified permissions was an NFSv3 client, the permissions are UNIX NFSv3 mode bits. If the last client was an NFSv4 client, the permissions are NFSv4 ACLs. If the last client was an SMB client, the permissions are Windows NTFS ACLs.

The unified security style is only available with infinite volumes, which are no longer supported in ONTAP 9.5 and later releases. For more information, see [FlexGroup volumes management overview](#).

Beginning with ONTAP 9.2, the `show-effective-permissions` parameter to the `vserver security file-directory` command enables you to display effective permissions granted to a Windows or UNIX user on the specified file or folder path. In addition, the optional parameter `-share-name` enables you to display the effective share permission.

 ONTAP initially sets some default file permissions. By default, the effective security style on all data in UNIX, mixed, and unified security style volumes is UNIX and the effective permissions type is UNIX mode bits (0755 unless specified otherwise) until configured by a client as allowed by the default security style. By default, the effective security style on all data in NTFS security style volumes is NTFS and has an ACL allowing full control to everyone.

#### Where and when to set security styles

Security styles can be set on FlexVol volumes (both root or data volumes) and qtrees. Security styles can be set manually at the time of creation, inherited automatically, or changed at a later time.

#### Decide which security style to use on SVMs

To help you decide which security style to use on a volume, you should consider two factors. The primary factor is the type of administrator that manages the file system. The secondary factor is the type of user or service that accesses the data on the volume.

When you configure the security style on a volume, you should consider the needs of your environment to

ensure that you select the best security style and avoid issues with managing permissions. The following considerations can help you decide:

| Security style | Choose if...                                                                                                                                                                                                                                |
|----------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| UNIX           | <ul style="list-style-type: none"><li>The file system is managed by a UNIX administrator.</li><li>The majority of users are NFS clients.</li><li>An application accessing the data uses a UNIX user as the service account.</li></ul>       |
| NTFS           | <ul style="list-style-type: none"><li>The file system is managed by a Windows administrator.</li><li>The majority of users are SMB clients.</li><li>An application accessing the data uses a Windows user as the service account.</li></ul> |
| Mixed          | <ul style="list-style-type: none"><li>The file system is managed by both UNIX and Windows administrators and users consist of both NFS and SMB clients.</li></ul>                                                                           |

#### How security style inheritance works

If you do not specify the security style when creating a new FlexVol volume or a qtree, it inherits its security style in different ways.

Security styles are inherited in the following manner:

- A FlexVol volume inherits the security style of the root volume of its containing SVM.
- A qtree inherits the security style of its containing FlexVol volume.
- A file or directory inherits the security style of its containing FlexVol volume or qtree.

#### How ONTAP preserves UNIX permissions

When files in a FlexVol volume that currently have UNIX permissions are edited and saved by Windows applications, ONTAP can preserve the UNIX permissions.

When applications on Windows clients edit and save files, they read the security properties of the file, create a new temporary file, apply those properties to the temporary file, and then give the temporary file the original file name.

When Windows clients perform a query for the security properties, they receive a constructed ACL that exactly represents the UNIX permissions. The sole purpose of this constructed ACL is to preserve the file's UNIX permissions as files are updated by Windows applications to ensure that the resulting files have the same UNIX permissions. ONTAP does not set any NTFS ACLs using the constructed ACL.

#### Manage UNIX permissions using the Windows Security tab

If you want to manipulate UNIX permissions of files or folders in mixed security-style volumes or qtrees on SVMs, you can use the Security tab on Windows clients. Alternatively, you can use applications that can query and set Windows ACLs.

- Modifying UNIX permissions

You can use the Windows Security tab to view and change UNIX permissions for a mixed security-style volume or qtree. If you use the main Windows Security tab to change UNIX permissions, you must first remove the existing ACE you want to edit (this sets the mode bits to 0) before you make your changes. Alternatively, you can use the Advanced editor to change permissions.

If mode permissions are used, you can directly change the mode permissions for the listed UID, GID, and others (everyone else with an account on the computer). For example, if the displayed UID has r-x permissions, you can change the UID permissions to rwx.

- Changing UNIX permissions to NTFS permissions

You can use the Windows Security tab to replace UNIX security objects with Windows security objects on a mixed security-style volume or qtree where the files and folders have a UNIX effective security style.

You must first remove all listed UNIX permission entries before you can replace them with the desired Windows User and Group objects. You can then configure NTFS-based ACLs on the Windows User and Group objects. By removing all UNIX security objects and adding only Windows Users and Groups to a file or folder in a mixed security-style volume or qtree, you change the effective security style on the file or folder from UNIX to NTFS.

When changing permissions on a folder, the default Windows behavior is to propagate these changes to all subfolders and files. Therefore, you must change the propagation choice to the desired setting if you do not want to propagate a change in security style to all child folders, subfolders, and files.

### Configure security styles on SVM root volumes

You configure the storage virtual machine (SVM) root volume security style to determine the type of permissions used for data on the root volume of the SVM.

#### Steps

1. Use the `vserver create` command with the `-rootvolume-security-style` parameter to define the security style.

The possible options for the root volume security style are `unix`, `ntfs`, or `mixed`.

2. Display and verify the configuration, including the root volume security style of the SVM you created:

```
vserver show -vserver vserver_name
```

### Configure security styles on FlexVol volumes

You configure the FlexVol volume security style to determine the type of permissions used for data on FlexVol volumes of the storage virtual machine (SVM).

#### Steps

1. Perform one of the following actions:

| If the FlexVol volume... | Use the command...                                                                                               |
|--------------------------|------------------------------------------------------------------------------------------------------------------|
| Does not yet exist       | <code>volume create</code> and include the <code>-security-style</code> parameter to specify the security style. |

|                |                                                                                        |
|----------------|----------------------------------------------------------------------------------------|
| Already exists | volume modify and include the –security-style parameter to specify the security style. |
|----------------|----------------------------------------------------------------------------------------|

The possible options for the FlexVol volume security style are unix, ntfs, or mixed.

If you do not specify a security style when creating a FlexVol volume, the volume inherits the security style of the root volume.

For more information about the volume create or volume modify commands, see [Logical storage management](#).

2. To display the configuration, including the security style of the FlexVol volume you created, enter the following command:

```
volume show -volume volume_name -instance
```

### Configure security styles on qtrees

You configure the qtree volume security style to determine the type of permissions used for data on qtrees.

#### Steps

1. Perform one of the following actions:

| If the qtree...    | Use the command...                                                                           |
|--------------------|----------------------------------------------------------------------------------------------|
| Does not exist yet | volume qtree create and include the –security-style parameter to specify the security style. |
| Already exists     | volume qtree modify and include the –security-style parameter to specify the security style. |

The possible options for the qtree security style are unix, ntfs, or mixed.

If you do not specify a security style when creating a qtree, the default security style is mixed.

For more information about the volume qtree create or volume qtree modify commands, see [Logical storage management](#).

2. To display the configuration, including the security style of the qtree you created, enter the following command: volume qtree show -qtree qtree\_name -instance

### Set up file access using NFS

#### Set up file access using NFS overview

You must complete a number of steps to allow clients access to files on storage virtual machines (SVMs) using NFS. There are some additional steps that are optional depending on the current configuration of your environment.

For clients to be able to access files on SVMs using NFS, you must complete the following tasks:

1. Enable the NFS protocol on the SVM.

You must configure the SVM to allow data access from clients over NFS.

2. Create an NFS server on the SVM.

An NFS server is a logical entity on the SVM that enables the SVM to serve files over NFS. You must create the NFS server and specify the NFS protocol versions you want to allow.

3. Configure export policies on the SVM.

You must configure export policies to make volumes and qtrees available to clients.

4. Configure the NFS server with the appropriate security and other settings depending on the network and storage environment.

This step might include configuring Kerberos, LDAP, NIS, name mappings, and local users.

## Secure NFS access using export policies

### How export policies control client access to volumes or qtrees

Export policies contain one or more *export rules* that process each client access request. The result of the process determines whether the client is denied or granted access and what level of access. An export policy with export rules must exist on the storage virtual machine (SVM) for clients to access data.

You associate exactly one export policy with each volume or qtree to configure client access to the volume or qtree. The SVM can contain multiple export policies. This enables you to do the following for SVMs with multiple volumes or qtrees:

- Assign different export policies to each volume or qtree of the SVM for individual client access control to each volume or qtree in the SVM.
- Assign the same export policy to multiple volumes or qtrees of the SVM for identical client access control without having to create a new export policy for each volume or qtree.

If a client makes an access request that is not permitted by the applicable export policy, the request fails with a permission-denied message. If a client does not match any rule in the export policy, then access is denied. If an export policy is empty, then all accesses are implicitly denied.

You can modify an export policy dynamically on a system running ONTAP.

### Default export policy for SVMs

Each SVM has a default export policy that contains no rules. An export policy with rules must exist before clients can access data on the SVM. Each FlexVol volume contained in the SVM must be associated with an export policy.

When you create an SVM, the storage system automatically creates a default export policy called `default` for the root volume of the SVM. You must create one or more rules for the default export policy before clients can access data on the SVM. Alternatively, you can create a custom export policy with rules. You can modify and

rename the default export policy, but you cannot delete the default export policy.

When you create a FlexVol volume in its containing SVM, the storage system creates the volume and associates the volume with the default export policy for the root volume of the SVM. By default, each volume created in the SVM is associated with the default export policy for the root volume. You can use the default export policy for all volumes contained in the SVM, or you can create a unique export policy for each volume. You can associate multiple volumes with the same export policy.

#### How export rules work

Export rules are the functional elements of an export policy. Export rules match client access requests to a volume against specific parameters you configure to determine how to handle the client access requests.

An export policy must contain at least one export rule to allow access to clients. If an export policy contains more than one rule, the rules are processed in the order in which they appear in the export policy. The rule order is dictated by the rule index number. If a rule matches a client, the permissions of that rule are used and no further rules are processed. If no rules match, the client is denied access.

You can configure export rules to determine client access permissions using the following criteria:

- The file access protocol used by the client sending the request, for example, NFSv4 or SMB.
- A client identifier, for example, host name or IP address.

The maximum size for the `-clientmatch` field is 4096 characters.

- The security type used by the client to authenticate, for example, Kerberos v5, NTLM, or AUTH\_SYS.

If a rule specifies multiple criteria, the client must match all of them for the rule to apply.

Beginning with ONTAP 9.3, you can enable export policy configuration checking as a background job that records any rules violations in an error rule list. The `vserver export-policy config-checker` commands invoke the checker and display results, which you can use to verify your configuration and delete erroneous rules from the policy.

The commands only validate export configuration for host names, netgroups, and anonymous users.

#### Example

The export policy contains an export rule with the following parameters:

- `-protocol nfs3`
- `-clientmatch 10.1.16.0/255.255.255.0`
- `-rorule any`
- `-rwrule any`

The client access request is sent using the NFSv3 protocol and the client has the IP address 10.1.17.37.

Even though the client access protocol matches, the IP address of the client is in a different subnet from the one specified in the export rule. Therefore, client matching fails and this rule does not apply to this client.

### **Example**

The export policy contains an export rule with the following parameters:

- -protocol nfs
- -clientmatch 10.1.16.0/255.255.255.0
- -rorule any
- -rwrule any

The client access request is sent using the NFSv4 protocol and the client has the IP address 10.1.16.54.

The client access protocol matches and the IP address of the client is in the specified subnet. Therefore, client matching is successful and this rule applies to this client. The client gets read-write access regardless of its security type.

### **Example**

The export policy contains an export rule with the following parameters:

- -protocol nfs3
- -clientmatch 10.1.16.0/255.255.255.0
- -rorule any
- -rwrule krb5,ntlm

Client #1 has the IP address 10.1.16.207, sends an access request using the NFSv3 protocol, and authenticated with Kerberos v5.

Client #2 has the IP address 10.1.16.211, sends an access request using the NFSv3 protocol, and authenticated with AUTH\_SYS.

The client access protocol and IP address matches for both clients. The read-only parameter allows read-only access to all clients regardless of the security type they authenticated with. Therefore both clients get read-only access. However, only client #1 gets read-write access because it used the approved security type Kerberos v5 to authenticate. Client #2 does not get read-write access.

### **Manage clients with an unlisted security type**

When a client presents itself with a security type that is not listed in an access parameter of an export rule, you have the choice of either denying access to the client or mapping it to the anonymous user ID instead by using the option `none` in the access parameter.

A client might present itself with a security type that is not listed in an access parameter because it was authenticated with a different security type or was not authenticated at all (security type AUTH\_NONE). By default, the client is automatically denied access to that level. However, you can add the option `none` to the access parameter. As a result, clients with an unlisted security style are mapped to the anonymous user ID instead. The `-anon` parameter determines what user ID is assigned to those clients. The user ID specified for the `-anon` parameter must be a valid user that is configured with permissions you deem appropriate for the anonymous user.

Valid values for the `-anon` parameter range from 0 to 65535.

| User ID assigned to -anon | Resulting handling of client access requests                                                                                                                                                                                                                                  |
|---------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0 - 65533                 | The client access request is mapped to the anonymous user ID and gets access depending on the permissions configured for this user.                                                                                                                                           |
| 65534                     | The client access request is mapped to the user nobody and gets access depending on the permissions configured for this user. This is the default.                                                                                                                            |
| 65535                     | The access request from any client is denied when mapped to this ID and the client presents itself with security type AUTH_NONE. The access request from clients with user ID 0 is denied when mapped to this ID and the client presents itself with any other security type. |

When using the option `none`, it is important to remember that the `read-only` parameter is processed first. Consider the following guidelines when configuring export rules for clients with unlisted security types:

| Read-only includes <code>none</code> | Read-write includes <code>none</code> | Resulting access for clients with unlisted security types |
|--------------------------------------|---------------------------------------|-----------------------------------------------------------|
| No                                   | No                                    | Denied                                                    |
| No                                   | Yes                                   | Denied because read-only is processed first               |
| Yes                                  | No                                    | Read-only as anonymous                                    |
| Yes                                  | Yes                                   | Read-write as anonymous                                   |

### Example

The export policy contains an export rule with the following parameters:

- `-protocol nfs3`
- `-clientmatch 10.1.16.0/255.255.255.0`
- `-rorule sys,none`
- `-rwrule any`
- `-anon 70`

Client #1 has the IP address 10.1.16.207, sends an access request using the NFSv3 protocol, and authenticated with Kerberos v5.

Client #2 has the IP address 10.1.16.211, sends an access request using the NFSv3 protocol, and authenticated with AUTH\_SYS.

Client #3 has the IP address 10.1.16.234, sends an access request using the NFSv3 protocol, and did not authenticate (meaning security type AUTH\_NONE).

The client access protocol and IP address matches for all three clients. The read-only parameter allows read-only access to clients with their own user ID that authenticated with AUTH\_SYS. The read-only parameter allows read-only access as the anonymous user with user ID 70 to clients that authenticated using any other security type. The read-write parameter allows read-write access to any security type, but in this case only applies to clients already filtered by the read-only rule.

Therefore, clients #1 and #3 get read-write access only as the anonymous user with user ID 70. Client #2 gets read-write access with its own user ID.

### **Example**

The export policy contains an export rule with the following parameters:

- -protocol nfs3
- -clientmatch 10.1.16.0/255.255.255.0
- -rorule sys,none
- -rwrule none
- -anon 70

Client #1 has the IP address 10.1.16.207, sends an access request using the NFSv3 protocol, and authenticated with Kerberos v5.

Client #2 has the IP address 10.1.16.211, sends an access request using the NFSv3 protocol, and authenticated with AUTH\_SYS.

Client #3 has the IP address 10.1.16.234, sends an access request using the NFSv3 protocol, and did not authenticate (meaning security type AUTH\_NONE).

The client access protocol and IP address matches for all three clients. The read-only parameter allows read-only access to clients with their own user ID that authenticated with AUTH\_SYS. The read-only parameter allows read-only access as the anonymous user with user ID 70 to clients that authenticated using any other security type. The read-write parameter allows read-write access only as the anonymous user.

Therefore, client #1 and client #3 get read-write access only as the anonymous user with user ID 70. Client #2 gets read-only access with its own user ID but is denied read-write access.

### **How security types determine client access levels**

The security type that the client authenticated with plays a special role in export rules. You must understand how the security type determines the levels of access the client gets to a volume or qtree.

The three possible access levels are as follows:

1. Read-only
2. Read-write
3. Superuser (for clients with user ID 0)

Because the access level by security type is evaluated in this order, you must observe the following rules when

constructing access level parameters in export rules:

| For a client to get access level... | These access parameters must match the client's security type... |
|-------------------------------------|------------------------------------------------------------------|
| Normal user read-only               | Read-only (-rorule)                                              |
| Normal user read-write              | Read-only (-rorule) and read-write (-rwrule)                     |
| Superuser read-only                 | Read-only (-rorule) and -superuser                               |
| Superuser read-write                | Read-only (-rorule) and read-write (-rwrule) and -superuser      |

The following are valid security types for each of these three access parameters:

- any
- none
- never

This security type is not valid for use with the `-superuser` parameter.

- krb5
- krb5i
- krb5p
- ntlm
- sys

When matching a client's security type against each of the three access parameters, there are three possible outcomes:

| If the client's security type...                                                                          | Then the client...                                                                                                                                                         |
|-----------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Matches the one specified in the access parameter.                                                        | Gets access for that level with its own user ID.                                                                                                                           |
| Does not match the one specified, but the access parameter includes the option <code>none</code> .        | Gets access for that level but as the anonymous user with the user ID specified by the <code>-anon</code> parameter.                                                       |
| Does not match the one specified and the access parameter does not include the option <code>none</code> . | Does not get any access for that level. This does not apply to the <code>-superuser</code> parameter because it always includes <code>none</code> even when not specified. |

## Example

The export policy contains an export rule with the following parameters:

- `-protocol nfs3`

- `-clientmatch 10.1.16.0/255.255.255.0`
- `-rorule any`
- `-rwrule sys, krb5`
- `-superuser krb5`

Client #1 has the IP address 10.1.16.207, has user ID 0, sends an access request using the NFSv3 protocol, and authenticated with Kerberos v5.

Client #2 has the IP address 10.1.16.211, has user ID 0, sends an access request using the NFSv3 protocol, and authenticated with AUTH\_SYS.

Client #3 has the IP address 10.1.16.234, has user ID 0, sends an access request using the NFSv3 protocol, and did not authenticate (AUTH\_NONE).

The client access protocol and IP address matches all three clients. The read-only parameter allows read-only access to all clients regardless of security type. The read-write parameter allows read-write access to clients with their own user ID that authenticated with AUTH\_SYS or Kerberos v5. The superuser parameter allows superuser access to clients with user ID 0 that authenticated with Kerberos v5.

Therefore, client #1 gets superuser read-write access because it matches all three access parameters. Client #2 gets read-write access but not superuser access. Client #3 gets read-only access but not superuser access.

#### **Manage superuser access requests**

When you configure export policies, you need to consider what you want to happen if the storage system receives a client access request with user ID 0, meaning as a superuser, and set up your export rules accordingly.

In the UNIX world, a user with the user ID 0 is known as the superuser, typically called root, who has unlimited access rights on a system. Using superuser privileges can be dangerous for several reasons, including breach of system and data security.

By default, ONTAP maps clients presenting with user ID 0 to the anonymous user. However, you can specify the `-superuser` parameter in export rules to determine how to handle clients presenting with user ID 0 depending on their security type. The following are valid options for the `-superuser` parameter:

- any
- none

This is the default setting if you do not specify the `-superuser` parameter.

- krb5
- ntlm
- sys

There are two different ways how clients presenting with user ID 0 are handled, depending on the `-superuser` parameter configuration:

| If the <code>-superuser</code> parameter and the client's security type... | Then the client...                                                                                                                                                                                                                          |
|----------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Match                                                                      | Gets superuser access with user ID 0.                                                                                                                                                                                                       |
| Do not match                                                               | Gets access as the anonymous user with the user ID specified by the <code>-anon</code> parameter and its assigned permissions. This is regardless of whether the read-only or read-write parameter specifies the option <code>none</code> . |

If a client presents with user ID 0 to access a volume with NTFS security style and the `-superuser` parameter is set to `none`, ONTAP uses the name mapping for the anonymous user to obtain the proper credentials.

### Example

The export policy contains an export rule with the following parameters:

- `-protocol nfs3`
- `-clientmatch 10.1.16.0/255.255.255.0`
- `-rorule any`
- `-rwrule krb5,ntlm`
- `-anon 127`

Client #1 has the IP address 10.1.16.207, has user ID 746, sends an access request using the NFSv3 protocol, and authenticated with Kerberos v5.

Client #2 has the IP address 10.1.16.211, has user ID 0, sends an access request using the NFSv3 protocol, and authenticated with AUTH\_SYS.

The client access protocol and IP address matches for both clients. The read-only parameter allows read-only access to all clients regardless of the security type they authenticated with. However, only client #1 gets read-write access because it used the approved security type Kerberos v5 to authenticate.

Client #2 does not get superuser access. Instead, it gets mapped to anonymous because the `-superuser` parameter is not specified. This means it defaults to `none` and automatically maps user ID 0 to anonymous. Client #2 also only gets read-only access because its security type did not match the read-write parameter.

### Example

The export policy contains an export rule with the following parameters:

- `-protocol nfs3`
- `-clientmatch 10.1.16.0/255.255.255.0`
- `-rorule any`
- `-rwrule krb5,ntlm`
- `-superuser krb5`
- `-anon 0`

Client #1 has the IP address 10.1.16.207, has user ID 0, sends an access request using the NFSv3 protocol, and authenticated with Kerberos v5.

Client #2 has the IP address 10.1.16.211, has user ID 0, sends an access request using the NFSv3 protocol, and authenticated with AUTH\_SYS.

The client access protocol and IP address matches for both clients. The read-only parameter allows read-only access to all clients regardless of the security type they authenticated with. However, only client #1 gets read-write access because it used the approved security type Kerberos v5 to authenticate. Client #2 does not get read-write access.

The export rule allows superuser access for clients with user ID 0. Client #1 gets superuser access because it matches the user ID and security type for the read-only and -superuser parameters. Client #2 does not get read-write or superuser access because its security type does not match the read-write parameter or the -superuser parameter. Instead, client #2 is mapped to the anonymous user, which in this case has the user ID 0.

#### How ONTAP uses export policy caches

To improve system performance, ONTAP uses local caches to store information such as host names and netgroups. This enables ONTAP to process export policy rules more quickly than retrieving the information from external sources. Understanding what the caches are and what they do can help you troubleshoot client access issues.

You configure export policies to control client access to NFS exports. Each export policy contains rules, and each rule contains parameters to match the rule to clients requesting access. Some of these parameters require ONTAP to contact an external source, such as DNS or NIS servers, to resolve objects such as domain names, host names, or netgroups.

These communications with external sources take a small amount of time. To increase performance, ONTAP reduces the amount of time it takes to resolve export policy rule objects by storing information locally on each node in several caches.

| Cache name | Type of information stored                                                           |
|------------|--------------------------------------------------------------------------------------|
| Access     | Mappings of clients to corresponding export policies                                 |
| Name       | Mappings of UNIX user names to corresponding UNIX user IDs                           |
| ID         | Mappings of UNIX user IDs to corresponding UNIX user IDs and extended UNIX group IDs |
| Host       | Mappings of host names to corresponding IP addresses                                 |
| Netgroup   | Mappings of netgroups to corresponding IP addresses of members                       |
| Showmount  | List of exported directories from SVM namespace                                      |

If you change information on the external name servers in your environment after ONTAP retrieved and stored it locally, the caches might now contain outdated information. Although ONTAP refreshes caches automatically after certain time periods, different caches have different expiration and refresh times and algorithms.

Another possible reason for caches to contain outdated information is when ONTAP attempts to refresh cached information but encounters a failure when attempting to communicate with name servers. If this happens, ONTAP continues to use the information currently stored in the local caches to prevent client disruption.

As a result, client access requests that are supposed to succeed might fail, and client access requests that are supposed to fail might succeed. You can view and manually flush some of the export policy caches when troubleshooting such client access issues.

#### **How the access cache works**

ONTAP uses an access cache to store the results of export policy rule evaluation for client access operations to a volume or qtree. This results in performance improvements because the information can be retrieved much faster from the access cache than going through the export policy rule evaluation process every time a client sends an I/O request.

Whenever an NFS client sends an I/O request to access data on a volume or qtree, ONTAP must evaluate each I/O request to determine whether to grant or deny the I/O request. This evaluation involves checking every export policy rule of the export policy associated with the volume or qtree. If the path to the volume or qtree involves crossing one or more junction points, this might require performing this check for multiple export policies along the path.

Note that this evaluation occurs for every I/O request sent from an NFS client, such as read, write, list, copy and other operations; not just for initial mount requests.

After ONTAP has identified the applicable export policy rules and decided whether to allow or deny the request, ONTAP then creates an entry in the access cache to store this information.

When an NFS client sends an I/O request, ONTAP notes the IP address of the client, the ID of the SVM, and the export policy associated with the target volume or qtree, and first checks the access cache for a matching entry. If a matching entry exists in the access cache, ONTAP uses the stored information to allow or deny the I/O request. If a matching entry does not exist, ONTAP then goes through the normal process of evaluating all applicable policy rules as explained above.

Access cache entries that are not actively used are not refreshed. This reduces unnecessary and wasteful communication with external name servers.

Retrieving the information from the access cache is much faster than going through the entire export policy rule evaluation process for every I/O request. Therefore, using the access cache greatly improves performance by reducing the overhead of client access checks.

#### **How access cache parameters work**

Several parameters control the refresh periods for entries in the access cache. Understanding how these parameters work enables you to modify them to tune the access cache and balance performance with how recent the stored information is.

The access cache stores entries consisting of one or more export rules that apply to clients attempting to access volumes or qtrees. These entries are stored for a certain amount of time before they are refreshed. The

refresh time is determined by access cache parameters and depends on the type of access cache entry.

You can specify access cache parameters for individual SVMs. This allows the parameters to differ according to SVM access requirements. Access cache entries that are not actively used are not refreshed, which reduces unnecessary and wasteful communication with external name servers.

| Access cache entry type | Description                                                              | Refresh period in seconds                         |
|-------------------------|--------------------------------------------------------------------------|---------------------------------------------------|
| Positive entries        | Access cache entries that have not resulted in access denial to clients. | Minimum: 300<br>Maximum: 86,400<br>Default: 3,600 |
| Negative entries        | Access cache entries that have resulted in access denial to clients.     | Minimum: 60<br>Maximum: 86,400<br>Default: 3,600  |

### Example

An NFS client attempts to access a volume on a cluster. ONTAP matches the client to an export policy rule and determines that the client gets access based on the export policy rule configuration. ONTAP stores the export policy rule in the access cache as a positive entry. By default, ONTAP keeps the positive entry in the access cache for one hour (3,600 seconds), and then automatically refreshes the entry to keep the information current.

To prevent the access cache from filling up unnecessarily, there is an additional parameter to clear existing access cache entries that have not been used for a certain time period to decide client access. This `-harvest-timeout` parameter has an allowed range of 60 through 2,592,000 seconds and a default setting of 86,400 seconds.

### Remove an export policy from a qtree

If you decide you do not want a specific export policy assigned to a qtree any longer, you can remove the export policy by modifying the qtree to inherit the export policy of the containing volume instead. You can do this by using the `volume qtree modify` command with the `-export-policy` parameter and an empty name string ("").

### Steps

1. To remove an export policy from a qtree, enter the following command:

```
volume qtree modify -vserver vserver_name -qtree-path
/vol/volume_name/qtree_name -export-policy ""
```

2. Verify that the qtree was modified accordingly:

```
volume qtree show -qtree qtree_name -fields export-policy
```

### Validate qtree IDs for qtree file operations

ONTAP can perform an optional additional validation of qtree IDs. This validation ensures

that client file operation requests use a valid qtree ID and that clients can only move files within the same qtree. You can enable or disable this validation by modifying the `-validate-qtree-export` parameter. This parameter is enabled by default.

### About this task

This parameter is only effective when you have assigned an export policy directly to one or more qtrees on the storage virtual machine (SVM).

### Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Perform one of the following actions:

| If you want qtree ID validation to be... | Enter the following command...                                                        |
|------------------------------------------|---------------------------------------------------------------------------------------|
| Enabled                                  | <code>vserver nfs modify -vserver vserver_name -validate-qtree-export enabled</code>  |
| Disabled                                 | <code>vserver nfs modify -vserver vserver_name -validate-qtree-export disabled</code> |

3. Return to the admin privilege level:

```
set -privilege admin
```

### Export policy restrictions and nested junctions for FlexVol volumes

If you configured export policies to set a less restrictive policy on a nested junction but a more restrictive policy on a higher level junction, access to the lower level junction might fail.

You should ensure that higher level junctions have less restrictive export policies than lower level junctions.

### Using Kerberos with NFS for strong security

#### ONTAP support for Kerberos

Kerberos provides strong secure authentication for client/server applications. Authentication provides verification of user and process identities to a server. In the ONTAP environment, Kerberos provides authentication between storage virtual machines (SVMs) and NFS clients.

In ONTAP 9, the following Kerberos functionality is supported:

- Kerberos 5 authentication with integrity checking (krb5i)

Krb5i uses checksums to verify the integrity of each NFS message transferred between client and server. This is useful both for security reasons (for example, to ensure that data has not been tampered with) and for data integrity reasons (for example, to prevent data corruption when using NFS over unreliable networks).

- Kerberos 5 authentication with privacy checking (krb5p)

Krb5p uses checksums to encrypt all the traffic between client and the server. This is more secure and also incurs more load.

- 128-bit and 256-bit AES encryption

Advanced Encryption Standard (AES) is an encryption algorithm for securing electronic data. ONTAP now supports AES with 128-bit keys (AES-128) and AES with 256-bit keys (AES-256) encryption for Kerberos for stronger security.

- SVM-level Kerberos realm configurations

SVM administrators can now create Kerberos realm configurations at the SVM level. This means that SVM administrators no longer have to rely on the cluster administrator for Kerberos realm configuration and can create individual Kerberos realm configurations in a multi-tenancy environment.

#### Requirements for configuring Kerberos with NFS

Before you configure Kerberos with NFS on your system, you must verify that certain items in your network and storage environment are properly configured.

The steps to configure your environment depend on what version and type of client operating system, domain controller, Kerberos, DNS, etc., that you are using. Documenting all these variables is beyond the scope of this document. For more information, see the respective documentation for each component.

For a detailed example of how to set up ONTAP and Kerberos 5 with NFSv3 and NFSv4 in an environment using Windows Server 2008 R2 Active Directory and Linux hosts, see technical report 4073.

The following items should be configured first:

#### Network environment requirements

- Kerberos

You must have a working Kerberos setup with a key distribution center (KDC), such as Windows Active Directory based Kerberos or MIT Kerberos.

NFS servers must use `nfs` as the primary component of their machine principal.

- Directory service

You must use a secure directory service in your environment, such as Active Directory or OpenLDAP, that is configured to use LDAP over SSL/TLS.

- NTP

You must have a working time server running NTP. This is necessary to prevent Kerberos authentication failure due to time skew.

- Domain name resolution (DNS)

Each UNIX client and each SVM LIF must have a proper service record (SRV) registered with the KDC under forward and reverse lookup zones. All participants must be properly resolvable via DNS.

- User accounts

Each client must have a user account in the Kerberos realm. NFS servers must use “nfs” as the primary component of their machine principal.

## NFS client requirements

- NFS

Each client must be properly configured to communicate over the network using NFSv3 or NFSv4.

Clients must support RFC1964 and RFC2203.

- Kerberos

Each client must be properly configured to use Kerberos authentication, including the following details:

- Encryption for TGS communication is enabled.  
AES-256 for strongest security.
- The most secure encryption type for TGT communication is enabled.
- The Kerberos realm and domain are configured correctly.
- GSS is enabled.

When using machine credentials:

- Do not run gssd with the `-n` parameter.
- Do not run kinit as the root user.

- Each client must use the most recent and updated operating system version.

This provides the best compatibility and reliability for AES encryption with Kerberos.

- DNS

Each client must be properly configured to use DNS for correct name resolution.

- NTP

Each client must be synchronizing with the NTP server.

- Host and domain information

Each client’s `/etc/hosts` and `/etc/resolv.conf` files must contain the correct host name and DNS information, respectively.

- Keytab files

Each client must have a keytab file from the KDC. The realm must be in uppercase letters. The encryption type must be AES-256 for strongest security.

- Optional: For best performance, clients benefit from having at least two network interfaces: one for communicating with the local area network and one for communicating with the storage network.

## **Storage system requirements**

- NFS license

The storage system must have a valid NFS license installed.

- CIFS license

The CIFS license is optional. It is only required for checking Windows credentials when using multiprotocol name mapping. It is not required in a strict UNIX-only environment.

- SVM

You must have at least one SVM configured on the system.

- DNS on the SVM

You must have configured DNS on each SVM.

- NFS server

You must have configured NFS on the SVM.

- AES encryption

For strongest security, you must configure the NFS server to allow only AES-256 encryption for Kerberos.

- SMB server

If you are running a multiprotocol environment, you must have configured SMB on the SVM. The SMB server is required for multiprotocol name mapping.

- Volumes

You must have a root volume and at least one data volume configured for use by the SVM.

- Root volume

The root volume of the SVM must have the following configuration:

| Name           | Setting      |
|----------------|--------------|
| Security style | UNIX         |
| UID            | root or ID 0 |

| Name             | Setting      |
|------------------|--------------|
| GID              | root or ID 0 |
| UNIX permissions | 777          |

In contrast to the root volume, data volumes can have either security style.

- UNIX groups

The SVM must have the following UNIX groups configured:

| Group name | Group ID                                                       |
|------------|----------------------------------------------------------------|
| daemon     | 1                                                              |
| root       | 0                                                              |
| pcuser     | 65534 (created automatically by ONTAP when you create the SVM) |

- UNIX users

The SVM must have the following UNIX users configured:

| User name | User ID | Primary group ID | Comment                                                                                                                           |
|-----------|---------|------------------|-----------------------------------------------------------------------------------------------------------------------------------|
| nfs       | 500     | 0                | Required for GSS INIT phase The first component of the NFS client user SPN is used as the user.                                   |
| pcuser    | 65534   | 65534            | Required for NFS and CIFS multiprotocol use Created and added to the pcuser group automatically by ONTAP when you create the SVM. |
| root      | 0       | 0                | Required for mounting                                                                                                             |

The nfs user is not required if a Kerberos-UNIX name mapping exists for the SPN of the NFS client user.

- Export policies and rules

You must have configured export policies with the necessary export rules for the root and data volumes and qtrees. If all volumes of the SVM are accessed over Kerberos, you can set the export rule options `-rorule`, `-rwrule`, and `-superuser` for the root volume to `krb5`, `krb5i`, or `krb5p`.

- Kerberos-UNIX name mapping

If you want the user identified by the NFS client user SPN to have root permissions, you must create a name mapping to root.

### Specify the user ID domain for NFSv4

To specify the user ID domain, you can set the `-v4-id-domain` option.

#### About this task

By default, ONTAP uses the NIS domain for NFSv4 user ID mapping, if one is set. If an NIS domain is not set, the DNS domain is used. You might need to set the user ID domain if, for example, you have multiple user ID domains. The domain name must match the domain configuration on the domain controller. It is not required for NFSv3.

#### Step

1. Enter the following command:

```
vserver nfs modify -vserver vserver_name -v4-id-domain NIS_domain_name
```

## Configure name services

### How ONTAP name service switch configuration works

ONTAP stores name service configuration information in a table that is the equivalent of the `/etc/nsswitch.conf` file on UNIX systems. You must understand the function of the table and how ONTAP uses it so that you can configure it appropriately for your environment.

The ONTAP name service switch table determines which name service sources ONTAP consults in which order to retrieve information for a certain type of name service information. ONTAP maintains a separate name service switch table for each SVM.

## Database types

The table stores a separate name service list for each of the following database types:

| Database type | Defines name service sources for...   | Valid sources are... |
|---------------|---------------------------------------|----------------------|
| hosts         | Converting host names to IP addresses | files, dns           |

| <b>Database type</b> | <b>Defines name service sources for...</b> | <b>Valid sources are...</b> |
|----------------------|--------------------------------------------|-----------------------------|
| group                | Looking up user group information          | files, nis, ldap            |
| passwd               | Looking up user information                | files, nis, ldap            |
| netgroup             | Looking up netgroup information            | files, nis, ldap            |
| namemap              | Mapping user names                         | files, ldap                 |

## Source types

The sources specify which name service source to use for retrieving the appropriate information.

| <b>Specify source type...</b> | <b>To look up information in...</b>                                            | <b>Managed by the command families...</b>                                                                                                                                     |
|-------------------------------|--------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| files                         | Local source files                                                             | vserver services name-service unix-user vserver services name-service unix-group<br><br>vserver services name-service netgroup<br><br>vserver services name-service dns hosts |
| nis                           | External NIS servers as specified in the NIS domain configuration of the SVM   | vserver services name-service nis-domain                                                                                                                                      |
| ldap                          | External LDAP servers as specified in the LDAP client configuration of the SVM | vserver services name-service ldap                                                                                                                                            |
| dns                           | External DNS servers as specified in the DNS configuration of the SVM          | vserver services name-service dns                                                                                                                                             |

Even if you plan to use NIS or LDAP for both data access and SVM administration authentication, you should still include `files` and configure local users as a fallback in case NIS or LDAP authentication fails.

## Protocols used to access external sources

To access the servers for external sources, ONTAP uses the following protocols:

| External name service source | Protocol used for access |
|------------------------------|--------------------------|
| NIS                          | UDP                      |
| DNS                          | UDP                      |
| LDAP                         | TCP                      |

### Example

The following example displays the name service switch configuration for the SVM svm\_1:

```
cluster1::>*> vserver services name-service ns-switch show -vserver svm_1
 Source
Vserver Database Order

svm_1 hosts files,
 dns
svm_1 group files
svm_1 passwd files
svm_1 netgroup nis,
 files
```

To look up IP addresses for hosts, ONTAP first consults local source files. If the query does not return any results, DNS servers are checked next.

To look up user or group information, ONTAP consults only local sources files. If the query does not return any results, the lookup fails.

To look up netgroup information, ONTAP first consults external NIS servers. If the query does not return any results, the local netgroup file is checked next.

There are no name service entries for name mapping in the table for the SVM svm\_1. Therefore, ONTAP consults only local source files by default.

### Use LDAP

#### LDAP Overview

An LDAP (Lightweight Directory Access Protocol) server enables you to centrally maintain user information. If you store your user database on an LDAP server in your environment, you can configure your storage system to look up user information in your existing LDAP database.

- Before configuring LDAP for ONTAP, you should verify that your site deployment meets best practices for LDAP server and client configuration. In particular, the following conditions must be met:

- The domain name of the LDAP server must match the entry on the LDAP client.
- The LDAP user password hash types supported by the LDAP server must include those supported by ONTAP:
  - CRYPT (all types) and SHA-1 (SHA, SSHA).
  - Beginning with ONTAP 9.8, SHA-2 hashes (SHA-256, SSH-384, SHA-512, SSHA-256, SSHA-384, and SSHA-512) are also supported.
- If the LDAP server requires session security measures, you must configure them in the LDAP client.

The following session security options are available:

- LDAP signing (provides data integrity checking) and LDAP signing and sealing (provides data integrity checking and encryption)
- START TLS
- LDAPS (LDAP over TLS or SSL)
- To enable signed and sealed LDAP queries, the following services must be configured:
  - LDAP servers must support the GSSAPI (Kerberos) SASL mechanism.
  - LDAP servers must have DNS A/AAAA records as well as PTR records set up on the DNS server.
  - Kerberos servers must have SRV records present on the DNS server.
- To enable START TLS or LDAPS, the following points should be considered.
  - It is a NetApp best practice to use Start TLS rather than LDAPS.
  - If LDAPS is used, the LDAP server must be enabled for TLS or for SSL in ONTAP 9.5 and later. SSL is not supported in ONTAP 9.0-9.4.
  - A certificate server must already be configured in the domain.
- To enable LDAP referral chasing (in ONTAP 9.5 and later), the following conditions must be satisfied:
  - Both domains should be configured with one of the following trust relationships:
    - Two-way
    - One-way, where the primary trusts the referral domain
    - Parent-child
  - DNS must be configured to resolve all referred server names.
  - Domain passwords should be same to authenticate when `--bind-as-cifs-server` set to true.

The following configurations are not supported with LDAP referral chasing.

- For all ONTAP versions:
- LDAP clients on an admin SVM
- For ONTAP 9.8 and earlier (they are supported in 9.9.1 and later):
  - LDAP signing and sealing (the `-session-security` option)
  - Encrypted TLS connections (the `-use-start-tls` option)
  - Communications over LDAPS port 636 (the `-use-ldaps-for-ad-ldap` option)

- Beginning with ONTAP 9.11.1, you can use [LDAP fast bind for nsswitch authentication](#).

- You must enter an LDAP schema when configuring the LDAP client on the SVM.

In most cases, one of the default ONTAP schemas will be appropriate. However, if the LDAP schema in your environment differs from these, you must create a new LDAP client schema for ONTAP before creating the LDAP client. Consult with your LDAP administrator about requirements for your environment.

- Using LDAP for host name resolution is not supported.

For additional information, see [NetApp Technical Report 4835: How to Configure LDAP in ONTAP](#).

### LDAP signing and sealing concepts

Beginning with ONTAP 9, you can configure signing and sealing to enable LDAP session security on queries to an Active Directory (AD) server. You must configure the NFS server security settings on the storage virtual machine (SVM) to correspond to those on the LDAP server.

Signed confirms the integrity of the LDAP payload data using secret key technology. Sealing encrypts the LDAP payload data to avoid transmitting sensitive information in clear text. An *LDAP Security Level* option indicates whether the LDAP traffic needs to be signed, signed and sealed, or neither. The default is none. test

LDAP signing and sealing on SMB traffic is enabled on the SVM with the `-session-security-for-ad -ldap` option to the `vserver cifs security modify` command.

### LDAPS concepts

You must understand certain terms and concepts about how ONTAP secures LDAP communication. ONTAP can use START TLS or LDAPS for setting up authenticated sessions between Active Directory-integrated LDAP servers or UNIX-based LDAP servers.

### Terminology

There are certain terms that you should understand about how ONTAP uses LDAPS to secure LDAP communication.

- **LDAP**

(Lightweight Directory Access Protocol) A protocol for accessing and managing information directories. LDAP is used as an information directory for storing objects such as users, groups, and netgroups. LDAP also provides directory services that manage these objects and fulfill LDAP requests from LDAP clients.

- **SSL**

(Secure Sockets Layer) A protocol developed for sending information securely over the Internet. It has been deprecated in favor of TLS. SSL is not supported in ONTAP 9.0-9.4.

- **TLS**

(Transport Layer Security) An IETF standards track protocol that is based on the earlier SSL specifications. It is the successor to SSL.

- **LDAPS (LDAP over SSL or TLS)**

A protocol that uses TLS or SSL to secure communication between LDAP clients and LDAP servers. The terms *LDAP over SSL* and *LDAP over TLS* are sometimes used interchangeably; TLS is supported by ONTAP 9 and later, SSL is supported by ONTAP 9.5 and later.

- In ONTAP 9.5-9.8, LDAPS can only be enabled on port 636. To do so, use the `-use-ldaps-for-ad-ldap` parameter with the `vserver cifs security modify` command.
- Beginning with ONTAP 9.9.1, LDAPS can be enabled on any port, although port 636 remains the default. To do so, set the `-ldaps-enabled` parameter to `true` and specify the desired `-port` parameter. For more information, see the `vserver services name-service ldap client create` man page

It is a NetApp best practice to use Start TLS rather than LDAPS.

- **Start TLS**

(Also known as *start\_tls*, *STARTTLS*, and *StartTLS*) A mechanism to provide secure communication by using the TLS protocols.

ONTAP uses STARTTLS for securing LDAP communication, and uses the default LDAP port (389) to communicate with the LDAP server. The LDAP server must be configured to allow connections over LDAP port 389; otherwise, LDAP TLS connections from the SVM to the LDAP server fail.

## How ONTAP uses LDAPS

ONTAP supports TLS server authentication, which enables the SVM LDAP client to confirm the LDAP server's identity during the bind operation. TLS-enabled LDAP clients can use standard techniques of public-key cryptography to check that a server's certificate and public ID are valid and have been issued by a certificate authority (CA) listed in the client's list of trusted CAs.

LDAP supports STARTTLS to encrypt communications using TLS. STARTTLS begins as a plaintext connection over the standard LDAP port (389), and that connection is then upgraded to TLS.

ONTAP supports the following:

- LDAPS for SMB-related traffic between the Active Directory-integrated LDAP servers and the SVM
- LDAPS for LDAP traffic for name mapping and other UNIX information

Either Active Directory-integrated LDAP servers or UNIX-based LDAP servers can be used to store information for LDAP name mapping and other UNIX information, such as users, groups, and netgroups.

- Self-signed root CA certificates

When using an Active-Directory integrated LDAP, the self-signed root certificate is generated when the Windows Server Certificate Service is installed in the domain. When using an UNIX-based LDAP server for LDAP name mapping, the self-signed root certificate is generated and saved by using means appropriate to that LDAP application.

By default, LDAPS is disabled.

## Enable LDAP RFC2307bis support

If you want to use LDAP and require the additional capability to use nested group

memberships, you can configure ONTAP to enable LDAP RFC2307bis support.

## What you'll need

You must have created a copy of one of the default LDAP client schemas that you want to use.

## About this task

In LDAP client schemas, group objects use the memberUid attribute. This attribute can contain multiple values and lists the names of the users that belong to that group. In RFC2307bis enabled LDAP client schemas, group objects use the uniqueMember attribute. This attribute can contain the full distinguished name (DN) of another object in the LDAP directory. This enables you to use nested groups because groups can have other groups as members.

The user should not be a member of more than 256 groups including nested groups. ONTAP ignores any groups over the 256 group limit.

By default, RFC2307bis support is disabled.

RFC2307bis support is enabled automatically in ONTAP when an LDAP client is created with the MS-AD-BIS schema.

For additional information, see [NetApp Technical Report 4835: How to Configure LDAP in ONTAP](#).

## Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Modify the copied RFC2307 LDAP client schema to enable RFC2307bis support:

```
vserver services name-service ldap client schema modify -vserver vserver_name
-schema schema-name -enable-rfc2307bis true
```

3. Modify the schema to match the object class supported in the LDAP server:

```
vserver services name-service ldap client schema modify -vserver vserver-name
-schema schema_name -group-of-unique-names-object-class object_class
```

4. Modify the schema to match the attribute name supported in the LDAP server:

```
vserver services name-service ldap client schema modify -vserver vserver-name
-schema schema_name -unique-member-attribute attribute_name
```

5. Return to the admin privilege level:

```
set -privilege admin
```

## Configuration options for LDAP directory searches

You can optimize LDAP directory searches, including user, group, and netgroup information, by configuring the ONTAP LDAP client to connect to LDAP servers in the most appropriate way for your environment. You need to understand when the default LDAP base and scope search values suffice and which parameters to specify when

custom values are more appropriate.

LDAP client search options for user, group, and netgroup information can help avoid failed LDAP queries, and therefore failed client access to storage systems. They also help ensure that the searches are as efficient as possible to avoid client performance issues.

### Default base and scope search values

The LDAP base is the default base DN that the LDAP client uses to perform LDAP queries. All searches, including user, group, and netgroup searches, are done using the base DN. This option is appropriate when your LDAP directory is relatively small and all relevant entries are located in the same DN.

If you do not specify a custom base DN, the default is `root`. This means that each query searches the entire directory. Although this maximizes the chances of success of the LDAP query, it can be inefficient and result in significantly decreased performance with large LDAP directories.

The LDAP base scope is the default search scope that the LDAP client uses to perform LDAP queries. All searches, including user, group, and netgroup searches, are done using the base scope. It determines whether the LDAP query searches only the named entry, entries one level below the DN, or the entire subtree below the DN.

If you do not specify a custom base scope, the default is `subtree`. This means that each query searches the entire subtree below the DN. Although this maximizes the chances of success of the LDAP query, it can be inefficient and result in significantly decreased performance with large LDAP directories.

### Custom base and scope search values

Optionally, you can specify separate base and scope values for user, group, and netgroup searches. Limiting the search base and scope of queries this way can significantly improve performance because it limits the search to a smaller subsection of the LDAP directory.

If you specify custom base and scope values, they override the general default search base and scope for user, group, and netgroup searches. The parameters to specify custom base and scope values are available at the advanced privilege level.

| LDAP client parameter... | Specifies custom...                                                                                                                                           |
|--------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>-base-dn</code>    | Base DN for all LDAP searches<br>Multiple values can be entered if needed (for example, if LDAP referral chasing is enabled in ONTAP 9.5 and later releases). |
| <code>-base-scope</code> | Base scope for all LDAP searches                                                                                                                              |
| <code>-user-dn</code>    | Base DNs for all LDAP user searches<br>This parameter also applies to user name-mapping searches.                                                             |
| <code>-user-scope</code> | Base scope for all LDAP user searches<br>This parameter also applies to user name-mapping searches.                                                           |
| <code>-group-dn</code>   | Base DNs for all LDAP group searches                                                                                                                          |

|                 |                                           |
|-----------------|-------------------------------------------|
| -group-scope    | Base scope for all LDAP group searches    |
| -netgroup-dn    | Base DNs for all LDAP netgroup searches   |
| -netgroup-scope | Base scope for all LDAP netgroup searches |

## Multiple custom base DN values

If your LDAP directory structure is more complex, it might be necessary for you to specify multiple base DNs to search multiple parts of your LDAP directory for certain information. You can specify multiple DNs for the user, group, and netgroup DN parameters by separating them with a semicolon (;) and enclosing the entire DN search list with double quotes (""). If a DN contains a semicolon, you must add an escape character (\) immediately before the semicolon in the DN.

Note that the scope applies to the entire list of DNs specified for the corresponding parameter. For example, if you specify a list of three different user DNs and subtree for the user scope, then LDAP user searches search the entire subtree for each of the three specified DNs.

Beginning with ONTAP 9.5, you can also specify LDAP *referral chasing*, which allows the ONTAP LDAP client to refer look-up requests to other LDAP servers if an LDAP referral response is not returned by the primary LDAP server. The client uses that referral data to retrieve the target object from the server described in the referral data. To search for objects present in the referred LDAP servers, the base-dn of the referred objects can be added to the base-dn as part of LDAP client configuration. However, referred objects are only looked up when referral chasing is enabled (using the `-referral-enabled true` option) during LDAP client creation or modification.

## Improve performance of LDAP directory netgroup-by-host searches

If your LDAP environment is configured to allow netgroup-by-host searches, you can configure ONTAP to take advantage of this and perform netgroup-by-host searches. This can significantly speed up netgroup searches and reduce possible NFS client access issues due to latency during netgroup searches.

### What you'll need

Your LDAP directory must contain a `netgroup.byhost` map.

Your DNS servers should contain both forward (A) and reverse (PTR) lookup records for NFS clients.

When you specify IPv6 addresses in netgroups, you must always shorten and compress each address as specified in RFC 5952.

### About this task

NIS servers store netgroup information in three separate maps called `netgroup`, `netgroup.byuser`, and `netgroup.byhost`. The purpose of the `netgroup.byuser` and `netgroup.byhost` maps is to speed up netgroup searches. ONTAP can perform netgroup-by-host searches on NIS servers for improved mount response times.

By default, LDAP directories do not have such a `netgroup.byhost` map like NIS servers. It is possible, though, with the help of third-party tools, to import a NIS `netgroup.byhost` map into LDAP directories to enable fast netgroup-by-host searches. If you have configured your LDAP environment to allow netgroup-by-

host searches, you can configure the ONTAP LDAP client with the `netgroup.byhost` map name, DN, and search scope for faster netgroup-by-host searches.

Receiving the results for netgroup-by-host searches faster enables ONTAP to process export rules faster when NFS clients request access to exports. This reduces the chance of delayed access due to netgroup search latency issues.

## Steps

1. Obtain the exact full distinguished name of the NIS `netgroup.byhost` map you imported into your LDAP directory.

The map DN can vary depending on the third-party tool you used for import. For best performance, you should specify the exact map DN.

2. Set the privilege level to advanced: `set -privilege advanced`

3. Enable netgroup-by-host searches in the LDAP client configuration of the storage virtual machine (SVM):  
`vserver services name-service ldap client modify -vserver vserver_name -client -config config_name -is-netgroup-byhost-enabled true -netgroup-byhost-dn netgroup-by-host_map_distinguished_name -netgroup-byhost-scope netgroup-by-host_search_scope`

`-is-netgroup-byhost-enabled {true|false}` enables or disables netgroup-by-host search for LDAP directories. The default is `false`.

`-netgroup-byhost-dn netgroup-by-host_map_distinguished_name` specifies the distinguished name of the `netgroup.byhost` map in the LDAP directory. It overrides the base DN for netgroup-by-host searches. If you do not specify this parameter, ONTAP uses the base DN instead.

`-netgroup-byhost-scope {base|onelevel|subtree}` specifies the search scope for netgroup-by-host searches. If you do not specify this parameter, the default is `subtree`.

If the LDAP client configuration does not exist yet, you can enable netgroup-by-host searches by specifying these parameters when creating a new LDAP client configuration using the `vserver services name-service ldap client create` command.

Beginning with ONTAP 9.2, the field `-ldap-servers` replaces the field `-servers`. This new field can take either a hostname or an IP address for the LDAP server.

4. Return to the admin privilege level: `set -privilege admin`

## Example

The following command modifies the existing LDAP client configuration named “`ldap_corp`” to enable netgroup-by-host searches using the `netgroup.byhost` map named “`nisMapName="netgroup.byhost",dc=corp,dc=example,dc=com`” and the default search scope `subtree`:

```
cluster1::> vserver services name-service ldap client modify -vserver vs1
-client-config ldap_corp -is-netgroup-byhost-enabled true -netgroup-byhost
-dn nisMapName="netgroup.byhost",dc=corp,dc=example,dc=com
```

## After you finish

The `netgroup.byhost` and `netgroup` maps in the directory must be kept in sync at all times to avoid client access issues.

## Related information

### Use LDAP fast bind for nsswitch authentication

Beginning with ONTAP 9.11.1, you can take advantage of LDAP *fast bind* functionality (also known as *concurrent bind*) for faster and simpler client authentication requests. To use this functionality, the LDAP server must support fast bind functionality.

#### About this task

Without fast bind, ONTAP uses LDAP simple bind to authenticate admin users with the LDAP server. With this authentication method, ONTAP sends a user or group name to the LDAP server, receives the stored hash password, and compares the server hash code with the hash passcode generated locally from the user password. If they are identical, ONTAP grants login permission.

With fast bind functionality, ONTAP sends only user credentials (user name and password) to the LDAP server through a secure connection. The LDAP server then validates these credentials and instructs ONTAP to grant login permissions.

One advantage of fast bind is that there is no need for ONTAP to support every new hashing algorithm supported by LDAP servers, because password hashing is performed by the LDAP server.

#### [Learn about using fast bind.](#)

You can use existing LDAP client configurations for LDAP fast bind. However, it is strongly recommended that the LDAP client be configured for TLS or LDAPS; otherwise, the password is sent over the wire in plain text.

To enable LDAP fast bind in an ONTAP environment, you must satisfy these requirements:

- ONTAP admin users must be configured on an LDAP server that supports fast bind.
- The ONTAP SVM must be configured for LDAP in the name services switch (nsswitch) database.
- ONTAP admin user and group accounts must be configured for nsswitch authentication using fast bind.

#### Steps

1. Confirm with your LDAP administrator that LDAP fast bind is supported on the LDAP server.
2. Ensure that ONTAP admin user credentials are configured on the LDAP server.
3. Verify that the admin or data SVM is configured correctly for LDAP fast bind.
  - a. To confirm that the LDAP fast bind server is listed in the LDAP client configuration, enter:

```
vserver services name-service ldap client show
```

[Learn about LDAP client configuration.](#)

- b. To confirm that `ldap` is one of the configured sources for the nsswitch `passwd` database, enter:

```
vserver services name-service ns-switch show
```

[Learn about nsswitch configuration.](#)

4. Ensure that admin users are authenticating with nsswitch and that LDAP fast bind authentication is enabled in their accounts.
  - For existing users, enter `security login modify` and verify the following parameter settings:

```
-authentication-method nsswitch
-is-ldap-fastbind true
```
  - For new admin users, see [Enable LDAP or NIS account access](#).

## Display LDAP statistics

Beginning with ONTAP 9.2, you can display LDAP statistics for storage virtual machines (SVMs) on a storage system to monitor the performance and diagnose issues.

### What you'll need

- You must have configured an LDAP client on the SVM.
- You must have identified LDAP objects from which you can view data.

### Step

1. View the performance data for counter objects:

```
statistics show
```

### Examples

The following example shows the performance data for object `secd_external_service_op`:

```

cluster::*> statistics show -vserver vserverName -object
secd_external_service_op -instance "vserverName:LDAP (NIS & Name
Mapping):GetUserInfoFromName:1.1.1.1"

Object: secd_external_service_op
Instance: vserverName:LDAP (NIS & Name
Mapping):GetUserInfoFromName:1.1.1.1
Start-time: 4/13/2016 22:15:38
End-time: 4/13/2016 22:15:38
Scope: vserverName
Counter Value

instance_name vserverName:LDAP (NIS & Name
Mapping):GetUserInfoFromName:
1.1.1.1
last_modified_time 1460610787
node_name nodeName
num_not_found_responses 1
num_request_failures 1
num_requests_sent 1
num_responses_received 1
num_successful_responses 0
num_timeouts 0
operation GetUserInfoFromName
process_name secd
request_latency 52131us

```

## Configure name mappings

### Configure name mappings overview

ONTAP uses name mapping to map SMB identities to UNIX identities, Kerberos identities to UNIX identities, and UNIX identities to SMB identities. It needs this information to obtain user credentials and provide proper file access regardless of whether they are connecting from an NFS client or a SMB client.

There are two exceptions where you do not have to use name mapping:

- You configure a pure UNIX environment and do not plan to use SMB access or NTFS security style on volumes.
- You configure the default user to be used instead.

In this scenario, name mapping is not required because instead of mapping every individual client credential all client credentials are mapped to the same default user.

Note that you can use name mapping only for users, not for groups.

However, you can map a group of individual users to a specific user. For example, you can map all AD users that start or end with the word SALES to a specific UNIX user and to the user's UID.

#### How name mapping works

When ONTAP has to map credentials for a user, it first checks the local name mapping database and LDAP server for an existing mapping. Whether it checks one or both and in which order is determined by the name service configuration of the SVM.

- For Windows to UNIX mapping

If no mapping is found, ONTAP checks whether the lowercase Windows user name is a valid user name in the UNIX domain. If this does not work, it uses the default UNIX user provided that it is configured. If the default UNIX user is not configured and ONTAP cannot obtain a mapping this way either, mapping fails and an error is returned.

- For UNIX to Windows mapping

If no mapping is found, ONTAP tries to find a Windows account that matches the UNIX name in the SMB domain. If this does not work, it uses the default SMB user, provided that it is configured. If the default SMB user is not configured and ONTAP cannot obtain a mapping this way either, mapping fails and an error is returned.

Machine accounts are mapped to the specified default UNIX user by default. If no default UNIX user is specified, machine account mappings fail.

- Beginning with ONTAP 9.5, you can map machine accounts to users other than the default UNIX user.
- In ONTAP 9.4 and earlier, you cannot map machine accounts to other users.

Even if name mappings for machine accounts are defined, the mappings are ignored.

#### Multidomain searches for UNIX user to Windows user name mappings

ONTAP supports multidomain searches when mapping UNIX users to Windows users. All discovered trusted domains are searched for matches to the replacement pattern until a matching result is returned. Alternatively, you can configure a list of preferred trusted domains, which is used instead of the discovered trusted domain list and is searched in order until a matching result is returned.

#### How domain trusts affect UNIX user to Windows user name mapping searches

To understand how multidomain user name mapping works, you must understand how domain trusts work with ONTAP. Active Directory trust relationships with the SMB server's home domain can be a bidirectional trust or can be one of two types of unidirectional trusts, either an inbound trust or an outbound trust. The home domain is the domain to which the SMB server on the SVM belongs.

- *Bidirectional trust*

With bidirectional trusts, both domains trust each other. If the SMB server's home domain has a bidirectional trust with another domain, the home domain can authenticate and authorize a user belonging to the trusted domain and vice versa.

UNIX user to Windows user name mapping searches can be performed only on domains with bidirectional trusts between the home domain and the other domain.

- *Outbound trust*

With an outbound trust, the home domain trusts the other domain. In this case, the home domain can authenticate and authorize a user belonging to the outbound trusted domain.

A domain with an outbound trust with the home domain is *not* searched when performing UNIX user to Windows user name mapping searches.

- *Inbound trust*

With an inbound trust, the other domain trusts the SMB server's home domain. In this case, the home domain cannot authenticate or authorize a user belonging to the inbound trusted domain.

A domain with an inbound trust with the home domain is *not* searched when performing UNIX user to Windows user name mapping searches.

### How wildcards (\*) are used to configure multidomain searches for name mapping

Multidomain name mapping searches are facilitated by the use of wildcards in the domain section of the Windows user name. The following table illustrates how to use wildcards in the domain part of a name mapping entry to enable multidomain searches:

| Pattern | Replacement      | Result                                                                                                                                                                                                                                                                                                                                                        |
|---------|------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| root    | *\\administrator | The UNIX user "root" is mapped to the user named "administrator". All trusted domains are searched in order until the first matching user named "administrator" is found.                                                                                                                                                                                     |
| *       | *\\*             | Valid UNIX users are mapped to the corresponding Windows users. All trusted domains are searched in order until the first matching user with that name is found.<br><br> The pattern *\\* is only valid for name mapping from UNIX to Windows, not the other way around. |

### How multidomain name searches are performed

You can choose one of two methods for determining the list of trusted domains used for multidomain name searches:

- Use the automatically discovered bidirectional trust list compiled by ONTAP
- Use the preferred trusted domain list that you compile

If a UNIX user is mapped to a Windows user with a wildcard used for the domain section of the user name, the Windows user is looked up in all the trusted domains as follows:

- If a preferred trusted-domain list is configured, the mapped Windows user is looked up in this search list only, in order.
- If a preferred list of trusted domains is not configured, then the Windows user is looked up in all the bidirectional trusted domains of the home domain.
- If there are no bidirectionally trusted domains for the home domain, the user is looked up in the home domain.

If a UNIX user is mapped to a Windows user without a domain section in the user name, the Windows user is looked up in the home domain.

#### Name mapping conversion rules

An ONTAP system keeps a set of conversion rules for each SVM. Each rule consists of two pieces: a *pattern* and a *replacement*. Conversions start at the beginning of the appropriate list and perform a substitution based on the first matching rule. The pattern is a UNIX-style regular expression. The replacement is a string containing escape sequences representing subexpressions from the pattern, as in the UNIX sed program.

#### Create a name mapping

You can use the `vserver name-mapping create` command to create a name mapping. You use name mappings to enable Windows users to access UNIX security style volumes and the reverse.

#### About this task

For each SVM, ONTAP supports up to 12,500 name mappings for each direction.

#### Step

1. Create a name mapping:

```
vserver name-mapping create -vserver vserver_name -direction {krb-unix|win-unix|unix-win} -position integer -pattern text -replacement text
```

The `-pattern` and `-replacement` statements can be formulated as regular expressions. You can also use the `-replacement` statement to explicitly deny a mapping to the user by using the null replacement string " " (the space character). See the `vserver name-mapping create` man page for details.

When Windows-to-UNIX mappings are created, any SMB clients that have open connections to the ONTAP system at the time the new mappings are created must log out and log back in to see the new mappings.

#### Examples

The following command creates a name mapping on the SVM named vs1. The mapping is a mapping from UNIX to Windows at position 1 in the priority list. The mapping maps the UNIX user johnd to the Windows user ENG\JohnDoe.

```
vs1::> vserver name-mapping create -vserver vs1 -direction unix-win
-position 1 -pattern johnd
-replacement "ENG\\JohnDoe"
```

The following command creates another name mapping on the SVM named vs1. The mapping is a mapping from Windows to UNIX at position 1 in the priority list. Here the pattern and replacement include regular expressions. The mapping maps every CIFS user in the domain ENG to users in the LDAP domain associated with the SVM.

```
vs1::> vserver name-mapping create -vserver vs1 -direction win-unix
-position 1 -pattern "ENG\\(.+)"
-replacement "\1"
```

The following command creates another name mapping on the SVM named vs1. Here the pattern includes “\$” as an element in the Windows user name that must be escaped. The mapping maps the windows user ENG\john\$ops to UNIX user john\_ops.

```
vs1::> vserver name-mapping create -direction win-unix -position 1
-pattern ENG\\john\\$ops
-replacement john_ops
```

#### Configure the default user

You can configure a default user to use if all other mapping attempts fail for a user, or if you do not want to map individual users between UNIX and Windows. Alternatively, if you want authentication of non-mapped users to fail, you should not configure a default user.

#### About this task

For CIFS authentication, if you do not want to map each Windows user to an individual UNIX user, you can instead specify a default UNIX user.

For NFS authentication, if you do not want to map each UNIX user to an individual Windows user, you can instead specify a default Windows user.

#### Step

1. Perform one of the following actions:

| If you want to...                  | Enter the following command...                           |
|------------------------------------|----------------------------------------------------------|
| Configure the default UNIX user    | vserver cifs options modify -default-unix-user user_name |
| Configure the default Windows user | vserver nfs modify -default-win-user user_name           |

## Commands for managing name mappings

There are specific ONTAP commands for managing name mappings.

| If you want to...                                                                                                                     | Use this command...                                                                                                  |
|---------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------|
| Create a name mapping                                                                                                                 | vserver name-mapping create                                                                                          |
| Insert a name mapping at a specific position                                                                                          | vserver name-mapping insert                                                                                          |
| Display name mappings                                                                                                                 | vserver name-mapping show                                                                                            |
| Exchange the position of two name mappings<br>NOTE: A swap is not allowed when name-mapping is configured with an ip-qualifier entry. | vserver name-mapping swap                                                                                            |
| Modify a name mapping                                                                                                                 | vserver name-mapping modify                                                                                          |
| Delete a name mapping                                                                                                                 | vserver name-mapping delete                                                                                          |
| Validate the correct name mapping                                                                                                     | vserver security file-directory show-effective-permissions -vserver vs1 -win-user-name user1 -path / -share-name sh1 |

See the man page for each command for more information.

## Enable access for Windows NFS clients

ONTAP supports file access from Windows NFSv3 clients. This means that clients running Windows operating systems with NFSv3 support can now access files on NFSv3 exports on the cluster. To successfully use this functionality, you must properly configure the storage virtual machine (SVM) and be aware of certain requirements and limitations.

### What you'll need

NFSv3 must be enabled on the SVM.

### About this task

By default, Windows NFSv3 client support is disabled.

Windows NFSv3 clients do not support the network status monitor (NSM) protocol. As a result, Windows NFSv3 client sessions might experience disruptions during storage failover and volume move operations.

### Steps

1. Enable Windows NFSv3 client support:

```
vserver nfs modify -vserver vserver_name -v3-ms-dos-client enabled
```

2. On all SVMs that support Windows NFSv3 clients, disable the `-enable-ejukebox` and `-v3-connection-drop` parameters: `vserver nfs modify -vserver vserver_name -enable-ejukebox false -v3-connection-drop disabled`

Windows NFSv3 clients can now mount exports on the storage system.

3. Ensure that each Windows NFSv3 client uses hard mounts by specifying the `-o mtype=hard` option.

This is required to ensure reliable mounts.

```
mount -o mtype=hard \\10.53.33.10\vol\vol1 z:\
```

## Enable the display of NFS exports on NFS clients

NFS clients can use the `showmount -e` command to see a list of exports available from an ONTAP NFS server. This can help users identify the file system they want to mount.

Beginning with ONTAP 9.2, ONTAP allows NFS clients to view the export list by default. In earlier releases, the `showmount` option of the `vserver nfs modify` command must be enabled explicitly. For viewing the export list, NFSv3 should be enabled on the SVM.

### Example

The following command shows the `showmount` feature on the SVM named vs1:

```
clusterl : : > vserver nfs show -vserver vs1 -fields showmount
vserver showmount

vs1 enabled
```

The following command executed on an NFS client displays the list of exports on an NFS server with the IP address 10.63.21.9:

```
showmount -e 10.63.21.9
Export list for 10.63.21.9:
/ unix (everyone)
/ unix/unix1 (everyone)
/ unix/unix2 (everyone)
/ (everyone)
```

## Manage file access using NFS

### Enable or disable NFSv3

You can enable or disable NFSv3 by modifying the `-v3` option. This allows file access for clients using the NFSv3 protocol. By default, NFSv3 is enabled.

### Step

1. Perform one of the following actions:

| If you want to... | Enter the command...                                  |
|-------------------|-------------------------------------------------------|
| Enable NFSv3      | vserver nfs modify -vserver vserver_name -v3 enabled  |
| Disable NFSv3     | vserver nfs modify -vserver vserver_name -v3 disabled |

### Enable or disable NFSv4.0

You can enable or disable NFSv4.0 by modifying the `-v4.0` option. This allows file access for clients using the NFSv4.0 protocol. In ONTAP 9.9.1, NFSv4.0 is enabled by default; in earlier releases, it is disabled by default.

#### Step

1. Perform one of the following actions:

| If you want to... | Enter the following command...                          |
|-------------------|---------------------------------------------------------|
| Enable NFSv4.0    | vserver nfs modify -vserver vserver_name -v4.0 enabled  |
| Disable NFSv4.0   | vserver nfs modify -vserver vserver_name -v4.0 disabled |

### Enable or disable NFSv4.1

You can enable or disable NFSv4.1 by modifying the `-v4.1` option. This allows file access for clients using the NFSv4.1 protocol. In ONTAP 9.9.1, NFSv4.1 is enabled by default; in earlier releases, it is disabled by default.

#### Step

1. Perform one of the following actions:

| If you want to... | Enter the following command...                          |
|-------------------|---------------------------------------------------------|
| Enable NFSv4.1    | vserver nfs modify -vserver vserver_name -v4.1 enabled  |
| Disable NFSv4.1   | vserver nfs modify -vserver vserver_name -v4.1 disabled |

### Manage NFSv4 storepool limits

Beginning with ONTAP 9.13, administrators can enable their NFSv4 servers to deny

resources to NFSv4 clients when they have reached per client storepool resource limits. When clients consume too many NFSv4 storepool resources this can lead to other NFSv4 clients getting blocked due to unavailability of NFSv4 storepool resources.

Enabling this feature also allows customers to view the active storepool resource consumption by each client. This makes it easier to identify clients exhausting system resources, and makes it possible to impose per client resource limits.

#### **View storepool resources consumed**

The `vserver nfs storepool show` command shows the number of storepool resources consumed. A storepool is a pool of resources used by NFSv4 clients.

## Step

1. As an administrator, run the `vserver nfs storepool show` command to display the storepool information of NFSv4 clients.

## Example

This example displays the storepool information of NFSv4 clients.

```
cluster1::*> vserver nfs storepool show

Node: node1

Vserver: vs1

Data-Ip: 10.0.1.1

Client-Ip Protocol IsTrunked OwnerCount OpenCount DelegCount LockCount

```

| Client-Ip | Protocol | IsTrunked | OwnerCount | OpenCount | DelegCount | LockCount |
|-----------|----------|-----------|------------|-----------|------------|-----------|
| 10.0.2.1  | nfs4.1   | true      | 2          | 1         | 0          | 4         |
| 10.0.2.2  | nfs4.2   | true      | 2          | 1         | 0          | 4         |

2 entries were displayed.

## **Enable or disable storepool limit controls**

Administrators can use the following commands to enable or disable storepool limit controls.

## Step

1. As an administrator, perform one of the following actions:

| If you want to...                | Enter the following command...                              |
|----------------------------------|-------------------------------------------------------------|
| Enable storepool limit controls  | vserver nfs storepool config modify -limit-enforce enabled  |
| Disable storepool limit controls | vserver nfs storepool config modify -limit-enforce disabled |

#### View a list of blocked clients

If the storepool limit is enabled, administrators can see which clients have been blocked upon reaching their per client resource threshold. Administrators can use the following command to see which clients have been marked as blocked clients.

#### Steps

1. Use the `vserver nfs storepool blocked-client show` command to display the NFSv4 blocked client list.

#### Remove a client from the blocked client list

Clients that reach their per client threshold will be disconnected and added to the block-client cache. Administrators can use the following command to remove the client from the block client cache. This will allow the client to connect to the ONTAP NFSV4 server.

#### Steps

1. Use the `vserver nfs storepool blocked-client flush -client-ip <ip address>` command to flush the storepool blocked client cache.
2. Use the `vserver nfs storepool blocked-client show` command to verify the client has been removed from the block client cache.

#### Example

This example displays a blocked client with the IP address "10.2.1.1" being flushed from all the nodes.

```
cluster1::>vserver nfs storepool blocked-client flush -client-ip 10.2.1.1

cluster1::>vserver nfs storepool blocked-client show

Node: node1

Client IP

10.1.1.1

1 entries were displayed.
```

## Enable or disable pNFS

pNFS improves performance by allowing NFS clients to perform read/write operations on storage devices directly and in parallel, bypassing the NFS server as a potential bottleneck. To enable or disable pNFS (parallel NFS), you can modify the `-v4.1-pnfs` option.

| If the ONTAP release is... | The pNFS default is... |
|----------------------------|------------------------|
| 9.8 or later               | disabled               |
| 9.7 or earlier             | enabled                |

### What you'll need

NFSv4.1 support is required to be able to use pNFS.

If you want to enable pNFS, you must first disable NFS referrals. They cannot both be enabled at the same time.

If you use pNFS with Kerberos on SVMs, you must enable Kerberos on every LIF on the SVM.

### Step

1. Perform one of the following actions:

| If you want to... | Enter the command...                                                      |
|-------------------|---------------------------------------------------------------------------|
| Enable pNFS       | <code>vserver nfs modify -vserver vserver_name -v4.1-pnfs enabled</code>  |
| Disable pNFS      | <code>vserver nfs modify -vserver vserver_name -v4.1-pnfs disabled</code> |

## Control NFS access over TCP and UDP

You can enable or disable NFS access to storage virtual machines (SVMs) over TCP and UDP by modifying the `-tcp` and `-udp` parameters, respectively. This enables you to control whether NFS clients can access data over TCP or UDP in your environment.

### About this task

These parameters only apply to NFS. They do not affect auxiliary protocols. For example, if NFS over TCP is disabled, mount operations over TCP still succeed. To completely block TCP or UDP traffic, you can use export policy rules.

 You must turn off the SnapDiff RPC Server before you disable TCP for NFS to avoid a command failed error. You can disable TCP by using the command `vserver snapdiff-rpc-server off -vserver vserver name`.

### Step

1. Perform one of the following actions:

| If you want NFS access to be... | Enter the command...                                   |
|---------------------------------|--------------------------------------------------------|
| Enabled over TCP                | vserver nfs modify -vserver vserver_name -tcp enabled  |
| Disabled over TCP               | vserver nfs modify -vserver vserver_name -tcp disabled |
| Enabled over UDP                | vserver nfs modify -vserver vserver_name -udp enabled  |
| Disabled over UDP               | vserver nfs modify -vserver vserver_name -udp disabled |

### Control NFS requests from nonreserved ports

You can reject NFS mount requests from nonreserved ports by enabling the `-mount-rootonly` option. To reject all NFS requests from nonreserved ports, you can enable the `-nfs-rootonly` option.

#### About this task

By default, the option `-mount-rootonly` is enabled.

By default, the option `-nfs-rootonly` is disabled.

These options do not apply to the NULL procedure.

#### Step

1. Perform one of the following actions:

| If you want to...                                | Enter the command...                                              |
|--------------------------------------------------|-------------------------------------------------------------------|
| Allow NFS mount requests from nonreserved ports  | vserver nfs modify -vserver vserver_name -mount-rootonly disabled |
| Reject NFS mount requests from nonreserved ports | vserver nfs modify -vserver vserver_name -mount-rootonly enabled  |
| Allow all NFS requests from nonreserved ports    | vserver nfs modify -vserver vserver_name -nfs-rootonly disabled   |
| Reject all NFS requests from nonreserved ports   | vserver nfs modify -vserver vserver_name -nfs-rootonly enabled    |

### Handle NFS access to NTFS volumes or qtrees for unknown UNIX users

If ONTAP cannot identify UNIX users attempting to connect to volumes or qtrees with NTFS security style, it therefore cannot explicitly map the user to a Windows user. You

can configure ONTAP to either deny access to such users for stricter security or map them to a default Windows user to ensure a minimum level of access for all users.

### What you'll need

A default Windows user must be configured if you want to enable this option.

### About this task

If a UNIX user tries to access volumes or qtrees with NTFS security style, the UNIX user must first be mapped to a Windows user so that ONTAP can properly evaluate the NTFS permissions. However, if ONTAP cannot look up the name of the UNIX user in the configured user information name service sources, it cannot explicitly map the UNIX user to a specific Windows user. You can decide how to handle such unknown UNIX users in the following ways:

- Deny access to unknown UNIX users.

This enforces stricter security by requiring explicit mapping for all UNIX users to gain access to NTFS volumes or qtrees.

- Map unknown UNIX users to a default Windows user.

This provides less security but more convenience by ensuring that all users get a minimum level of access to NTFS volumes or qtrees through a default Windows user.

### Steps

- Set the privilege level to advanced:

```
set -privilege advanced
```

- Perform one of the following actions:

| If you want the default Windows user for unknown UNIX users... | Enter the command...                                                                        |
|----------------------------------------------------------------|---------------------------------------------------------------------------------------------|
| Enabled                                                        | vserver nfs modify -vserver vserver_name -map -unknown-uid-to-default-windows-user enabled  |
| Disabled                                                       | vserver nfs modify -vserver vserver_name -map -unknown-uid-to-default-windows-user disabled |

- Return to the admin privilege level:

```
set -privilege admin
```

### Considerations for clients that mount NFS exports using a nonreserved port

The `-mount-rootonly` option must be disabled on a storage system that must support clients that mount NFS exports using a nonreserved port even when the user is logged in as root. Such clients include Hummingbird clients and Solaris NFS/IPv6 clients.

If the `-mount-rootonly` option is enabled, ONTAP does not allow NFS clients that use nonreserved ports,

meaning ports with numbers higher than 1,023, to mount NFS exports.

## Perform stricter access checking for netgroups by verifying domains

By default, ONTAP performs an additional verification when evaluating client access for a netgroup. The additional check ensures that the client's domain matches the domain configuration of the storage virtual machine (SVM). Otherwise, ONTAP denies client access.

### About this task

When ONTAP evaluates export policy rules for client access and an export policy rule contains a netgroup, ONTAP must determine whether a client's IP address belongs to the netgroup. For this purpose, ONTAP converts the client's IP address to a host name using DNS and obtains a fully qualified domain name (FQDN).

If the netgroup file only lists a short name for the host and the short name for the host exists in multiple domains, it is possible for a client from a different domain to obtain access without this check.

To prevent this, ONTAP compares the domain that was returned from DNS for the host against the list of DNS domain names configured for the SVM. If it matches, access is allowed. If it does not match, access is denied.

This verification is enabled by default. You can manage it by modifying the `-netgroup-dns-domain-search` parameter, which is available at the advanced privilege level.

### Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Perform the desired action:

| If you want domain verification for netgroups to be... | Enter...                                                                                   |
|--------------------------------------------------------|--------------------------------------------------------------------------------------------|
| Enabled                                                | <code>vserver nfs modify -vserver vserver_name -netgroup-dns-domain-search enabled</code>  |
| Disabled                                               | <code>vserver nfs modify -vserver vserver_name -netgroup-dns-domain-search disabled</code> |

3. Set the privilege level to admin:

```
set -privilege admin
```

## Modify ports used for NFSv3 services

The NFS server on the storage system uses services such as mount daemon and Network Lock Manager to communicate with NFS clients over specific default network ports. In most NFS environments the default ports work correctly and do not require

modification, but if you want to use different NFS network ports in your NFSv3 environment, you can do so.

### What you'll need

Changing NFS ports on the storage system requires that all NFS clients reconnect to the system, so you should communicate this information to your users in advance of making the change.

### About this task

You can set the ports used by the NFS mount daemon, Network Lock Manager, Network Status Monitor, and NFS quota daemon services for each storage virtual machine (SVM). The port number change affects NFS clients accessing data over both TCP and UDP.

Ports for NFSv4 and NFSv4.1 cannot be changed.

### Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Disable access to NFS:

```
vserver nfs modify -vserver vserver_name -access false
```

3. Set the NFS port for the specific NFS service:

```
vserver nfs modify -vserver vserver_namenfs_port_parameterport_number
```

| NFS port parameter | Description            | Default port |
|--------------------|------------------------|--------------|
| -mountd-port       | NFS mount daemon       | 635          |
| -nlim-port         | Network Lock Manager   | 4045         |
| -nsm-port          | Network Status Monitor | 4046         |
| -rquotad-port      | NFS quota daemon       | 4049         |

Besides the default port, the allowed range of port numbers is 1024 through 65535. Each NFS service must use a unique port.

4. Enable access to NFS:

```
vserver nfs modify -vserver vserver_name -access true
```

5. Use the `network connections listening show` command to verify the port number changes.

6. Return to the admin privilege level:

```
set -privilege admin
```

### Example

The following commands set the NFS Mount Daemon port to 1113 on the SVM named vs1:

```
vs1::> set -privilege advanced
Warning: These advanced commands are potentially dangerous; use
 them only when directed to do so by NetApp personnel.
Do you want to continue? {y|n}: y

vs1::*> vserver nfs modify -vserver vs1 -access false

vs1::*> vserver nfs modify -vserver vs1 -mountd-port 1113

vs1::*> vserver nfs modify -vserver vs1 -access true

vs1::*> network connections listening show
Vserver Name Interface Name:Local Port Protocol/Service

Node: cluster1-01
Cluster cluster1-01_clus_1:7700 TCP/ctlopcp
vs1 data1:4046 TCP/sm
vs1 data1:4046 UDP/sm
vs1 data1:4045 TCP/nlm-v4
vs1 data1:4045 UDP/nlm-v4
vs1 data1:1113 TCP/mount
vs1 data1:1113 UDP/mount
...
vs1::*> set -privilege admin
```

### Commands for managing NFS servers

There are specific ONTAP commands for managing NFS servers.

| If you want to...    | Use this command... |
|----------------------|---------------------|
| Create an NFS server | vserver nfs create  |
| Display NFS servers  | vserver nfs show    |
| Modify an NFS server | vserver nfs modify  |
| Delete an NFS server | vserver nfs delete  |

|                                                                                                                                                                                                                                                               |                                                                       |
|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------|
| <p>Hide the .snapshot directory listing under NFSv3 mount points</p> <p> Explicit access to the .snapshot directory will still be allowed even if the option is enabled.</p> | <p>vserver nfs commands with the -v3-hide-snapshot option enabled</p> |
|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------|

See the man page for each command for more information.

## Troubleshoot name service issues

When clients experience access failures due to name service issues, you can use the vserver services name-service getxxbyyy command family to manually perform various name service lookups and examine the details and results of the lookup to help with troubleshooting.

### About this task

- For each command, you can specify the following:
  - Name of the node or storage virtual machine (SVM) to perform the lookup on.  
This enables you to test name service lookups for a specific node or SVM to narrow the search for a potential name service configuration issue.
  - Whether to show the source used for the lookup.  
This enables you to check whether the correct source was used.
- ONTAP selects the service for performing the lookup based on the configured name service switch order.
- These commands are available at the advanced privilege level.

### Steps

1. Perform one of the following actions:

| To retrieve the...               | Use the command...                                                                                                                        |
|----------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------|
| IP address of a host name        | vserver services name-service getxxbyyy<br>getaddrinfo vserver services name-<br>service getxxbyyy gethostbyname (IPv4<br>addresses only) |
| Members of a group by group ID   | vserver services name-service getxxbyyy<br>getgrbygid                                                                                     |
| Members of a group by group name | vserver services name-service getxxbyyy<br>getgrbyname                                                                                    |

|                                                                   |                                                                                                                                                         |
|-------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------|
| List of groups a user belongs to                                  | vserver services name-service getxxbyyyy<br>getgrlist                                                                                                   |
| Host name of an IP address                                        | vserver services name-service getxxbyyyy<br>getnameinfo vserver services name-<br>service getxxbyyyy gethostbyaddr (IPv4<br>addresses only)             |
| User information by user name                                     | vserver services name-service getxxbyyyy<br>getpwbyname You can test name resolution of RBAC<br>users by specifying the -use-rbac parameter as<br>true. |
| User information by user ID                                       | vserver services name-service getxxbyyyy<br>getpwbyuid<br>You can test name resolution of RBAC users by<br>specifying the -use-rbac parameter as true.  |
| Netgroup membership of a client                                   | vserver services name-service getxxbyyyy<br>netgrp                                                                                                      |
| Netgroup membership of a client using netgroup-by-<br>host search | vserver services name-service getxxbyyyy<br>netgrpbyhost                                                                                                |

The following example shows a DNS lookup test for the SVM vs1 by attempting to obtain the IP address for the host acast1.eng.example.com:

```
cluster1::>*> vserver services name-service getxxbyyyy getaddrinfo -vserver
vs1 -hostname acast1.eng.example.com -address-family all -show-source true
Source used for lookup: DNS
Host name: acast1.eng.example.com
Canonical Name: acast1.eng.example.com
IPv4: 10.72.8.29
```

The following example shows a NIS lookup test for the SVM vs1 by attempting to retrieve user information for a user with the UID 501768:

```

cluster1::*> vserver services name-service getxxbyyyy getpwbyuid -vserver
vs1 -userID 501768 -show-source true
Source used for lookup: NIS
pw_name: jsmith
pw_passwd: 1y8rA4XX7$/DDOXAvC2PC/IsNFozfIN0
pw_uid: 501768
pw_gid: 501768
pw_gecos:
pw_dir: /home/jsmith
pw_shell: /bin/bash

```

The following example shows an LDAP lookup test for the SVM vs1 by attempting to retrieve user information for a user with the name ldap1:

```

cluster1::*> vserver services name-service getxxbyyyy getpwbbyname -vserver
vs1 -username ldap1 -use-rbac false -show-source true
Source used for lookup: LDAP
pw_name: ldap1
pw_passwd: {crypt}JSPM6yc/iIIX6
pw_uid: 10001
pw_gid: 3333
pw_gecos: ldap1 user
pw_dir: /u/ldap1
pw_shell: /bin/csh

```

The following example shows a netgroup lookup test for the SVM vs1 by attempting to find out whether the client dnshost0 is a member of the netgroup lnetgroup136:

```

cluster1::*> vserver services name-service getxxbyyyy netgrp -vserver vs1
-netgroup lnetgroup136 -client dnshost0 -show-source true
Source used for lookup: LDAP
dnshost0 is a member of lnetgroup136

```

1. Analyze the results of the test you performed and take the necessary action.

| If the...                                                          | Check the...                      |
|--------------------------------------------------------------------|-----------------------------------|
| Host name or IP address lookup failed or yielded incorrect results | DNS configuration                 |
| Lookup queried an incorrect source                                 | Name service switch configuration |

|                                                                                                                |                                                                                                                                                                                                                      |
|----------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| User or group lookup failed or yielded incorrect results                                                       | Name service switch configuration<br>Source configuration (local files, NIS domain, LDAP client)<br><br>Network configuration (for example, LIFs and routes)                                                         |
| Host name lookup failed or timed out, and the DNS server does not resolve DNS short names (for example, host1) | DNS configuration for top-level domain (TLD) queries.<br>You can disable TLD queries using the <code>-is-tld-query-enabled false</code> option to the <code>vserver services name-service dns modify</code> command. |

### Verify name service connections

Beginning with ONTAP 9.2, you can check DNS and LDAP name servers to verify that they are connected to ONTAP. These commands are available at the admin privilege level.

#### About this task

You can check for a valid DNS or LDAP name service configuration on an as-needed basis using the name service configuration checker. This validation check can be initiated at the command line or in System Manager.

For DNS configurations, all servers are tested and need to be working for the configuration to be considered valid. For LDAP configurations, as long as any server is up, the configuration is valid. The name service commands apply the configuration checker unless the `skip-config-validation` field is true (the default is false).

#### Step

1. Use the appropriate command to check a name service configuration. The UI displays the status of the configured servers.

| To check...               | Use this command...                                   |
|---------------------------|-------------------------------------------------------|
| DNS configuration status  | <code>vserver services name-service dns check</code>  |
| LDAP configuration status | <code>vserver services name-service ldap check</code> |

```
cluster1::> vserver services name-service dns check -vserver vs0
```

| Vserver | Name Server | Status | Status Details            |
|---------|-------------|--------|---------------------------|
| vs0     | 10.11.12.13 | up     | Response time (msec) : 55 |
| vs0     | 10.11.12.14 | up     | Response time (msec) : 70 |
| vs0     | 10.11.12.15 | down   | Connection refused.       |

```
cluster1::> vserver services name-service ldap check -vserver vs0
```

```
| Vserver: vs0
| Client Configuration Name: c1
| LDAP Status: up
| LDAP Status Details: Successfully connected to LDAP server
| "10.11.12.13".
```

Configuration validation is successful if at least one of the configured servers (name-servers/ldap-servers) is reachable and providing the service. A warning is shown if some of the servers are not reachable.

### Commands for managing name service switch entries

You can manage name service switch entries by creating, displaying, modifying, and deleting them.

| If you want to...                   | Use this command...                            |
|-------------------------------------|------------------------------------------------|
| Create a name service switch entry  | vserver services name-service ns-switch create |
| Display name service switch entries | vserver services name-service ns-switch show   |
| Modify a name service switch entry  | vserver services name-service ns-switch modify |
| Delete a name service switch entry  | vserver services name-service ns-switch delete |

See the man page for each command for more information.

## Commands for managing name mappings

There are specific ONTAP commands for managing name mappings.

| If you want to...                                                                                                                     | Use this command...                                                                                                  |
|---------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------|
| Create a name mapping                                                                                                                 | vserver name-mapping create                                                                                          |
| Insert a name mapping at a specific position                                                                                          | vserver name-mapping insert                                                                                          |
| Display name mappings                                                                                                                 | vserver name-mapping show                                                                                            |
| Exchange the position of two name mappings<br>NOTE: A swap is not allowed when name-mapping is configured with an ip-qualifier entry. | vserver name-mapping swap                                                                                            |
| Modify a name mapping                                                                                                                 | vserver name-mapping modify                                                                                          |
| Delete a name mapping                                                                                                                 | vserver name-mapping delete                                                                                          |
| Validate the correct name mapping                                                                                                     | vserver security file-directory show-effective-permissions -vserver vsl -win-user-name user1 -path / -share-name sh1 |

See the man page for each command for more information.

### Commands for managing local UNIX users

There are specific ONTAP commands for managing local UNIX users.

| If you want to...                | Use this command...                                   |
|----------------------------------|-------------------------------------------------------|
| Create a local UNIX user         | vserver services name-service unix-user create        |
| Load local UNIX users from a URI | vserver services name-service unix-user load-from-uri |
| Display local UNIX users         | vserver services name-service unix-user show          |
| Modify a local UNIX user         | vserver services name-service unix-user modify        |
| Delete a local UNIX user         | vserver services name-service unix-user delete        |

See the man page for each command for more information.

### Commands for managing local UNIX groups

There are specific ONTAP commands for managing local UNIX groups.

| If you want to...                     | Use this command...                                    |
|---------------------------------------|--------------------------------------------------------|
| Create a local UNIX group             | vserver services name-service unix-group create        |
| Add a user to a local UNIX group      | vserver services name-service unix-group adduser       |
| Load local UNIX groups from a URI     | vserver services name-service unix-group load-from-uri |
| Display local UNIX groups             | vserver services name-service unix-group show          |
| Modify a local UNIX group             | vserver services name-service unix-group modify        |
| Delete a user from a local UNIX group | vserver services name-service unix-group deluser       |
| Delete a local UNIX group             | vserver services name-service unix-group delete        |

See the man page for each command for more information.

## Limits for local UNIX users, groups, and group members

ONTAP introduced limits for the maximum number of UNIX users and groups in the cluster, and commands to manage these limits. These limits can help avoid performance issues by preventing administrators from creating too many local UNIX users and groups in the cluster.

There is a limit for the combined number of local UNIX user groups and group members. There is a separate limit for local UNIX users. The limits are cluster-wide. Each of these new limits is set to a default value that you can modify up to a preassigned hard limit.

| Database                            | Default limit | Hard limit |
|-------------------------------------|---------------|------------|
| Local UNIX users                    | 32,768        | 65,536     |
| Local UNIX groups and group members | 32,768        | 65,536     |

### Manage limits for local UNIX users and groups

There are specific ONTAP commands for managing limits for local UNIX users and groups. Cluster administrators can use these commands to troubleshoot performance issues in the cluster believed to be related to excessive numbers of local UNIX users and groups.

#### About this task

These commands are available to the cluster administrator at the advanced privilege level.

#### Step

1. Perform one of the following actions:

| If you want to...                                 | Use the command...                           |
|---------------------------------------------------|----------------------------------------------|
| Display information about local UNIX user limits  | vserver services unix-user max-limit show    |
| Display information about local UNIX group limits | vserver services unix-group max-limit show   |
| Modify local UNIX user limits                     | vserver services unix-user max-limit modify  |
| Modify local UNIX group limits                    | vserver services unix-group max-limit modify |

See the man page for each command for more information.

## Commands for managing local netgroups

You can manage local netgroups by loading them from a URI, verifying their status across nodes, displaying them, and deleting them.

| If you want to...                           | Use the command...                                                                                     |
|---------------------------------------------|--------------------------------------------------------------------------------------------------------|
| Load netgroups from a URI                   | vserver services name-service netgroup load                                                            |
| Verify the status of netgroups across nodes | vserver services name-service netgroup status<br>Available at the advanced privilege level and higher. |
| Display local netgroups                     | vserver services name-service netgroup file show                                                       |
| Delete a local netgroup                     | vserver services name-service netgroup file delete                                                     |

See the man page for each command for more information.

## Commands for managing NIS domain configurations

There are specific ONTAP commands for managing NIS domain configurations.

| If you want to...                                    | Use this command...                                                                                                            |
|------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------|
| Create a NIS domain configuration                    | vserver services name-service nis-domain create                                                                                |
| Display NIS domain configurations                    | vserver services name-service nis-domain show                                                                                  |
| Display binding status of a NIS domain configuration | vserver services name-service nis-domain show-bound                                                                            |
| Display NIS statistics                               | vserver services name-service nis-domain show-statistics Available at the advanced privilege level and higher.                 |
| Clear NIS statistics                                 | vserver services name-service nis-domain clear-statistics Available at the advanced privilege level and higher.                |
| Modify a NIS domain configuration                    | vserver services name-service nis-domain modify                                                                                |
| Delete a NIS domain configuration                    | vserver services name-service nis-domain delete                                                                                |
| Enable caching for netgroup-by-host searches         | vserver services name-service nis-domain netgroup-database config modify Available at the advanced privilege level and higher. |

See the man page for each command for more information.

## Commands for managing LDAP client configurations

There are specific ONTAP commands for managing LDAP client configurations.

SVM administrators cannot modify or delete LDAP client configurations that were created by cluster administrators.

| If you want to...                    | Use this command...                                            |
|--------------------------------------|----------------------------------------------------------------|
| Create an LDAP client configuration  | vserver services name-service ldap client create               |
| Display LDAP client configurations   | vserver services name-service ldap client show                 |
| Modify an LDAP client configuration  | vserver services name-service ldap client modify               |
| Change the LDAP client BIND password | vserver services name-service ldap client modify-bind-password |
| Delete an LDAP client configuration  | vserver services name-service ldap client delete               |

See the man page for each command for more information.

## Commands for managing LDAP configurations

There are specific ONTAP commands for managing LDAP configurations.

| If you want to...            | Use this command...                       |
|------------------------------|-------------------------------------------|
| Create an LDAP configuration | vserver services name-service ldap create |
| Display LDAP configurations  | vserver services name-service ldap show   |
| Modify an LDAP configuration | vserver services name-service ldap modify |
| Delete an LDAP configuration | vserver services name-service ldap delete |

See the man page for each command for more information.

## Commands for managing LDAP client schema templates

There are specific ONTAP commands for managing LDAP client schema templates.

SVM administrators cannot modify or delete LDAP client schemas that were created by cluster administrators.

| If you want to... | Use this command... |
|-------------------|---------------------|
|                   |                     |

|                                       |                                                                                                               |
|---------------------------------------|---------------------------------------------------------------------------------------------------------------|
| Copy an existing LDAP schema template | vserver services name-service ldap client schema copy Available at the advanced privilege level and higher.   |
| Display LDAP schema templates         | vserver services name-service ldap client schema show                                                         |
| Modify an LDAP schema template        | vserver services name-service ldap client schema modify Available at the advanced privilege level and higher. |
| Delete an LDAP schema template        | vserver services name-service ldap client schema delete Available at the advanced privilege level and higher. |

See the man page for each command for more information.

### Commands for managing NFS Kerberos interface configurations

There are specific ONTAP commands for managing NFS Kerberos interface configurations.

| If you want to...                              | Use this command...                    |
|------------------------------------------------|----------------------------------------|
| Enable NFS Kerberos on a LIF                   | vserver nfs kerberos interface enable  |
| Display NFS Kerberos interface configurations  | vserver nfs kerberos interface show    |
| Modify an NFS Kerberos interface configuration | vserver nfs kerberos interface modify  |
| Disable NFS Kerberos on a LIF                  | vserver nfs kerberos interface disable |

See the man page for each command for more information.

### Commands for managing NFS Kerberos realm configurations

There are specific ONTAP commands for managing NFS Kerberos realm configurations.

| If you want to...                          | Use this command...               |
|--------------------------------------------|-----------------------------------|
| Create an NFS Kerberos realm configuration | vserver nfs kerberos realm create |
| Display NFS Kerberos realm configurations  | vserver nfs kerberos realm show   |

| If you want to...                          | Use this command...               |
|--------------------------------------------|-----------------------------------|
| Modify an NFS Kerberos realm configuration | vserver nfs kerberos realm modify |
| Delete an NFS Kerberos realm configuration | vserver nfs kerberos realm delete |

See the man page for each command for more information.

### Commands for managing export policies

There are specific ONTAP commands for managing export policies.

| If you want to...                         | Use this command...          |
|-------------------------------------------|------------------------------|
| Display information about export policies | vserver export-policy show   |
| Rename an export policy                   | vserver export-policy rename |
| Copy an export policy                     | vserver export-policy copy   |
| Delete an export policy                   | vserver export-policy delete |

See the man page for each command for more information.

### Commands for managing export rules

There are specific ONTAP commands for managing export rules.

| If you want to...                      | Use this command...               |
|----------------------------------------|-----------------------------------|
| Create an export rule                  | vserver export-policy rule create |
| Display information about export rules | vserver export-policy rule show   |
| Modify an export rule                  | vserver export-policy rule modify |
| Delete an export rule                  | vserver export-policy rule delete |

If you have configured multiple identical export rules matching different clients, be sure to keep them in sync when managing export rules.

See the man page for each command for more information.

## Configure the NFS credential cache

### Reasons for modifying the NFS credential cache time-to-live

ONTAP uses a credential cache to store information needed for user authentication for NFS export access to provide faster access and improve performance. You can configure how long information is stored in the credential cache to customize it for your environment.

There are several scenarios when modifying the NFS credential cache time-to-live (TTL) can help resolve issues. You should understand what these scenarios are as well as the consequences of making these modifications.

### Reasons

Consider changing the default TTL under the following circumstances:

| Issue                                                                                                                    | Remedial action                                                                                                                                                                      |
|--------------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| The name servers in your environment are experiencing performance degradation due to a high load of requests from ONTAP. | Increase the TTL for cached positive and negative credentials to reduce the number of requests from ONTAP to name servers.                                                           |
| The name server administrator made changes to allow access to NFS users that were previously denied.                     | Decrease the TTL for cached negative credentials to reduce the time NFS users have to wait for ONTAP to request fresh credentials from external name servers so they can get access. |
| The name server administrator made changes to deny access to NFS users that were previously allowed.                     | Reduce the TTL for cached positive credentials to reduce the time before ONTAP requests fresh credentials from external name servers so the NFS users are now denied access.         |

### Consequences

You can modify the length of time individually for caching positive and negative credentials. However, you should be aware of both the advantages and disadvantages of doing so.

| If you...                                   | The advantage is...                                                                                      | The disadvantage is...                                                                                     |
|---------------------------------------------|----------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------|
| Increase the positive credential cache time | ONTAP sends requests for credentials to name servers less frequently, reducing the load on name servers. | It takes longer to deny access to NFS users that previously were allowed access but are not anymore.       |
| Decrease the positive credential cache time | It takes less time to deny access to NFS users that previously were allowed access but are not anymore.  | ONTAP sends requests for credentials to name servers more frequently, increasing the load on name servers. |

| If you...                                   | The advantage is...                                                                                      | The disadvantage is...                                                                                     |
|---------------------------------------------|----------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------|
| Increase the negative credential cache time | ONTAP sends requests for credentials to name servers less frequently, reducing the load on name servers. | It takes longer to grant access to NFS users that previously were not allowed access but are now.          |
| Decrease the negative credential cache time | It takes less time to grant access to NFS users that previously were not allowed access but are now.     | ONTAP sends requests for credentials to name servers more frequently, increasing the load on name servers. |

#### Configure the time-to-live for cached NFS user credentials

You can configure the length of time that ONTAP stores credentials for NFS users in its internal cache (time-to-live, or TTL) by modifying the NFS server of the storage virtual machine (SVM). This enables you to alleviate certain issues related to high load on name servers or changes in credentials affecting NFS user access.

#### About this task

These parameters are available at the advanced privilege level.

#### Steps

- Set the privilege level to advanced:

```
set -privilege advanced
```

- Perform the desired action:

| If you want to modify the TTL for cached... | Use the command...                                                                                                                                                                                                                                                                                     |
|---------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Positive credentials                        | <pre>vserver nfs modify -vserver vserver_name -cached-cred-positive-ttl time_to_live</pre> <p>The TTL is measured in milliseconds. The default is 24 hours (86,400,000 milliseconds). The allowed range for this value is 1 minute (60000 milliseconds) through 7 days (604,800,000 milliseconds).</p> |
| Negative credentials                        | <pre>vserver nfs modify -vserver vserver_name -cached-cred-negative-ttl time_to_live</pre> <p>The TTL is measured in milliseconds. The default is 2 hours (7,200,000 milliseconds). The allowed range for this value is 1 minute (60000 milliseconds) through 7 days (604,800,000 milliseconds).</p>   |

- Return to the admin privilege level:

```
set -privilege admin
```

## Manage export policy caches

### Flush export policy caches

ONTAP uses several export policy caches to store information related to export policies for faster access. Flushing export policy caches manually (`vserver export-policy cache flush`) removes potentially outdated information and forces ONTAP to retrieve current information from the appropriate external resources. This can help resolve a variety of issues related to client access to NFS exports.

#### About this task

Export policy cache information might be outdated due to the following reasons:

- A recent change to export policy rules
- A recent change to host name records in name servers
- A recent change to netgroup entries in name servers
- Recovering from a network outage that prevented netgroups from being fully loaded

#### Steps

1. If you do not have name service cache enabled, perform one of the following actions in advance privilege mode:

| If you want to flush...                         | Enter the command...                                                                                                                                                                                                                                                    |
|-------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| All export policy caches (except for showmount) | <code>vserver export-policy cache flush<br/>-vserver vserver_name</code>                                                                                                                                                                                                |
| The export policy rules access cache            | <code>vserver export-policy cache flush<br/>-vserver vserver_name -cache access</code> You can include the optional <code>-node</code> parameter to specify the node on which you want to flush the access cache.                                                       |
| The host name cache                             | <code>vserver export-policy cache flush<br/>-vserver vserver_name -cache host</code>                                                                                                                                                                                    |
| The netgroup cache                              | <code>vserver export-policy cache flush<br/>-vserver vserver_name -cache netgroup</code> Processing of netgroups is resource intensive. You should only flush the netgroup cache if you are trying to resolve a client access issue that is caused by a stale netgroup. |
| The showmount cache                             | <code>vserver export-policy cache flush<br/>-vserver vserver_name -cache showmount</code>                                                                                                                                                                               |

2. If name service cache is enabled, perform one of the following actions:

| If you want to flush...              | Enter the command...                                                                                                                                                                                                                                                                                                    |
|--------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| The export policy rules access cache | vserver export-policy cache flush<br>-vserver vserver_name -cache access You can include the optional -node parameter to specify the node on which you want to flush the access cache.                                                                                                                                  |
| The host name cache                  | vserver services name-service cache hosts forward-lookup delete-all                                                                                                                                                                                                                                                     |
| The netgroup cache                   | vserver services name-service cache netgroups ip-to-netgroup delete-all vserver services name-service cache netgroups members delete-all Processing of netgroups is resource intensive. You should only flush the netgroup cache if you are trying to resolve a client access issue that is caused by a stale netgroup. |
| The showmount cache                  | vserver export-policy cache flush<br>-vserver vserver_name -cache showmount                                                                                                                                                                                                                                             |

#### Display the export policy netgroup queue and cache

ONTAP uses the netgroup queue when importing and resolving netgroups and it uses the netgroup cache to store the resulting information. When troubleshooting export policy netgroup related issues, you can use the `vserver export-policy netgroup queue show` and `vserver export-policy netgroup cache show` commands to display the status of the netgroup queue and the contents of the netgroup cache.

#### Step

1. Perform one of the following actions:

| To display the export policy netgroup... | Enter the command...                                                         |
|------------------------------------------|------------------------------------------------------------------------------|
| Queue                                    | <code>vserver export-policy netgroup queue show</code>                       |
| Cache                                    | <code>vserver export-policy netgroup cache show -vserver vserver_name</code> |

See the man page for each command for more information.

## Check whether a client IP address is a member of a netgroup

When troubleshooting NFS client access issues related to netgroups, you can use the `vserver export-policy netgroup check-membership` command to help determine whether a client IP is a member of a certain netgroup.

### About this task

Checking netgroup membership enables you to determine whether ONTAP is aware that a client is or is not member of a netgroup. It also lets you know whether the ONTAP netgroup cache is in a transient state while refreshing netgroup information. This information can help you understand why a client might be unexpectedly granted or denied access.

### Step

1. Check the netgroup membership of a client IP address: `vserver export-policy netgroup check-membership -vserver vserver_name -netgroup netgroup_name -client-ip client_ip`

The command can return the following results:

- The client is a member of the netgroup.

This was confirmed through a reverse lookup scan or a netgroup-by-host search.

- The client is a member of the netgroup.

It was found in the ONTAP netgroup cache.

- The client is not a member of the netgroup.
- The membership of the client cannot yet be determined because ONTAP is currently refreshing the netgroup cache.

Until this is done, membership cannot be explicitly ruled in or out. Use the `vserver export-policy netgroup queue show` command to monitor the loading of the netgroup and retry the check after it is finished.

### Example

The following example checks whether a client with the IP address 172.17.16.72 is a member of the netgroup mercury on the SVM vs1:

```
cluster1::> vserver export-policy netgroup check-membership -vserver vs1
-netgroup mercury -client-ip 172.17.16.72
```

## Optimize access cache performance

You can configure several parameters to optimize the access cache and find the right balance between performance and how current the information stored in the access cache is.

### About this task

When you configure the access cache refresh periods, keep the following in mind:

- Higher values mean entries stay longer in the access cache.

The advantage is better performance because ONTAP spends less resources on refreshing access cache entries. The disadvantage is that if export policy rules change and access cache entries become stale as a result, it takes longer to update them. As a result, clients that should get access might get denied, and clients that should get denied might get access.

- Lower values mean ONTAP refreshes access cache entries more often.

The advantage is that entries are more current and clients are more likely to be correctly granted or denied access. The disadvantage is a decrease in performance because ONTAP spends more resources refreshing access cache entries.

## Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Perform the desired action:

| To modify the...                    | Enter...                                                                                              |
|-------------------------------------|-------------------------------------------------------------------------------------------------------|
| Refresh period for positive entries | vserver export-policy access-cache config modify-all-vservers -refresh -period-positive timeout_value |
| Refresh period for negative entries | vserver export-policy access-cache config modify-all-vservers -refresh -period-negative timeout_value |
| Timeout period for old entries      | vserver export-policy access-cache config modify-all-vservers -harvest -timeout timeout_value         |

3. Verify the new parameter settings:

```
vserver export-policy access-cache config show-all-vservers
```

4. Return to the admin privilege level:

```
set -privilege admin
```

## Manage file locks

### About file locking between protocols

File locking is a method used by client applications to prevent a user from accessing a file previously opened by another user. How ONTAP locks files depends on the protocol of the client.

If the client is an NFS client, locks are advisory; if the client is an SMB client, locks are mandatory.

Because of differences between the NFS and SMB file locks, an NFS client might fail to access a file previously opened by an SMB application.

The following occurs when an NFS client attempts to access a file locked by an SMB application:

- In mixed or NTFS volumes, file manipulation operations such as `rm`, `rmdir`, and `mv` can cause the NFS application to fail.
- NFS read and write operations are denied by SMB deny-read and deny-write open modes, respectively.
- NFS write operations fail when the written range of the file is locked with an exclusive SMB bytelock.

In UNIX security-style volumes, NFS unlink and rename operations ignore SMB lock state and allow access to the file. All other NFS operations on UNIX security-style volumes honor SMB lock state.

#### How ONTAP treats read-only bits

The read-only bit is set on a file-by-file basis to reflect whether a file is writable (disabled) or read-only (enabled).

SMB clients that use Windows can set a per-file read-only bit. NFS clients do not set a per-file read-only bit because NFS clients do not have any protocol operations that use a per-file read-only bit.

ONTAP can set a read-only bit on a file when an SMB client that uses Windows creates that file. ONTAP can also set a read-only bit when a file is shared between NFS clients and SMB clients. Some software, when used by NFS clients and SMB clients, requires the read-only bit to be enabled.

For ONTAP to keep the appropriate read and write permissions on a file shared between NFS clients and SMB clients, it treats the read-only bit according to the following rules:

- NFS treats any file with the read-only bit enabled as if it has no write permission bits enabled.
- If an NFS client disables all write permission bits and at least one of those bits had previously been enabled, ONTAP enables the read-only bit for that file.
- If an NFS client enables any write permission bit, ONTAP disables the read-only bit for that file.
- If the read-only bit for a file is enabled and an NFS client attempts to discover permissions for the file, the permission bits for the file are not sent to the NFS client; instead, ONTAP sends the permission bits to the NFS client with the write permission bits masked.
- If the read-only bit for a file is enabled and an SMB client disables the read-only bit, ONTAP enables the owner's write permission bit for the file.
- Files with the read-only bit enabled are writable only by root.

Changes to file permissions take effect immediately on SMB clients, but might not take effect immediately on NFS clients if the NFS client enables attribute caching.

#### How ONTAP differs from Windows on handling locks on share path components

Unlike Windows, ONTAP does not lock each component of the path to an open file while the file is open. This behavior also affects SMB share paths.

Because ONTAP does not lock each component of the path, it is possible to rename a path component above the open file or share, which can cause problems for certain applications, or can cause the share path in the

SMB configuration to be invalid. This can cause the share to be inaccessible.

To avoid issues caused by renaming path components, you can apply Windows Access Control List (ACL) security settings that prevent users or applications from renaming critical directories.

Learn more about [How to prevent directories from being renamed while clients are accessing them](#).

#### Display information about locks

You can display information about the current file locks, including what types of locks are held and what the lock state is, details about byte-range locks, sharelock modes, delegation locks, and opportunistic locks, and whether locks are opened with durable or persistent handles.

#### About this task

The client IP address cannot be displayed for locks established through NFSv4 or NFSv4.1.

By default, the command displays information about all locks. You can use command parameters to display information about locks for a specific storage virtual machine (SVM) or to filter the command's output by other criteria.

The `vserver locks show` command displays information about four types of locks:

- Byte-range locks, which lock only a portion of a file.
- Share locks, which lock open files.
- Opportunistic locks, which control client-side caching over SMB.
- Delegations, which control client-side caching over NFSv4.x.

By specifying optional parameters, you can determine important information about each lock type. See the man page for the command for more information.

#### Step

1. Display information about locks by using the `vserver locks show` command.

#### Examples

The following example displays summary information for an NFSv4 lock on a file with the path `/vol1/file1`. The sharelock access mode is `write-deny_none`, and the lock was granted with write delegation:

```
cluster1::> vserver locks show

Vserver: vs0
Volume Object Path LIF Protocol Lock Type Client
----- ----- -----
----- -----
vol1 /vol1/file1 lif1 nfsv4 share-level -
 Sharelock Mode: write-deny_none
 delegation -
 Delegation Type: write
```

The following example displays detailed oplock and sharelock information about the SMB lock on a file with the path /data2/data2\_2/intro.pptx. A durable handle is granted on the file with a share lock access mode of write-deny\_none to a client with an IP address of 10.3.1.3. A lease oplock is granted with a batch oplock level:

```
cluster1::> vserver locks show -instance -path /data2/data2_2/intro.pptx
```

```
 Vserver: vs1
 Volume: data2_2
Logical Interface: lif2
 Object Path: /data2/data2_2/intro.pptx
 Lock UUID: 553cf484-7030-4998-88d3-1125adbba0b7

```

### **Breaking locks**

When file locks are preventing client access to files, you can display information about currently held locks, and then break specific locks. Examples of scenarios in which you might need to break locks include debugging applications.

#### **About this task**

The `vserver locks break` command is available only at the advanced privilege level and higher. The man page for the command contains detailed information.

#### **Steps**

1. To find the information you need to break a lock, use the `vserver locks show` command.

The man page for the command contains detailed information.

2. Set the privilege level to advanced:

```
set -privilege advanced
```

3. Perform one of the following actions:

| If you want to break a lock by specifying...       | Enter the command...                                                                           |
|----------------------------------------------------|------------------------------------------------------------------------------------------------|
| The SVM name, volume name, LIF name, and file path | <code>vserver locks break -vserver vserver_name -volume volume_name -path path -lif lif</code> |
| The lock ID                                        | <code>vserver locks break -lockid UUID</code>                                                  |

4. Return to the admin privilege level:

```
set -privilege admin
```

## How FPolicy first-read and first-write filters work with NFS

NFS clients experience high response time during high traffic of read/write requests when the FPolicy is enabled using an external FPolicy server with read/write operations as monitored events. For NFS clients, the use of first-read and first-write filters in the FPolicy reduces the number of FPolicy notifications and improves performance.

In NFS, the client does I/O on a file by fetching its handle. This handle might remain valid across reboots of the server and the client. Therefore, the client is free to cache the handle and send requests on it without retrieving handles again. In a regular session, lots of reads/write requests are sent to the file server. If notifications are generated for all these requests, it might result in the following issues:

- A larger load due to additional notification processing, and higher response time.
- A large number of notifications being sent to the FPolicy server even though the server unaffected by all of the notifications.

After receiving the first read/write request from a client for a particular file, a cache entry is created and the read/write count is incremented. This request is marked as the first-read/write operation, and an FPolicy event is generated. Before you plan and create your FPolicy filters for an NFS client, you should understand the basics of how FPolicy filters work.

- First-read: Filters the client read requests for first-read.

When this filter is used for NFS events, the `-file-session-io-grouping-count` and `-file-session-io-grouping-duration` settings determine the first-read request for which FPolicy is processed.

- First-write: Filters the client write requests for first-write.

When this filter is used for NFS events, the `-file-session-io-grouping-count` and `-file-session-io-grouping-duration` settings determine the first-write request for which FPolicy processed.

The following options are added in NFS servers database.

```
file-session-io-grouping-count: Number of I/O Ops on a File to Be Clubbed
and Considered as One Session
for Event Generation
file-session-io-grouping-duration: Duration for Which I/O Ops on a File to
Be Clubbed and Considered as
One Session for Event Generation
```

## Modify the NFSv4.1 server implementation ID

The NFSv4.1 protocol includes a server implementation ID that documents the server domain, name, and date. You can modify the server implementation ID default values. Changing the default values can be useful, for example, when gathering usage statistics or troubleshooting interoperability issues. For more information, see RFC 5661.

### About this task

The default values for the three options are as follows:

| Option                           | Option name                 | Default value        |
|----------------------------------|-----------------------------|----------------------|
| NFSv4.1 Implementation ID Domain | -v4.1-implementation-domain | netapp.com           |
| NFSv4.1 Implementation ID Name   | -v4.1-implementation-name   | Cluster version name |
| NFSv4.1 Implementation ID Date   | -v4.1-implementation-date   | Cluster version date |

## Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Perform one of the following actions:

| If you want to modify the NFSv4.1 implementation ID... | Enter the command...                                  |
|--------------------------------------------------------|-------------------------------------------------------|
| Domain                                                 | vserver nfs modify -v4.1-implementation-domain domain |
| Name                                                   | vserver nfs modify -v4.1-implementation-name name     |
| Date                                                   | vserver nfs modify -v4.1-implementation-date date     |

3. Return to the admin privilege level:

```
set -privilege admin
```

## Manage NFSv4 ACLs

### Benefits of enabling NFSv4 ACLs

There are many benefits to enabling NFSv4 ACLs.

The benefits of enabling NFSv4 ACLs include the following:

- Finer-grained control of user access for files and directories
- Better NFS security
- Improved interoperability with CIFS
- Removal of the NFS limitation of 16 groups per user

## How NFSv4 ACLs work

A client using NFSv4 ACLs can set and view ACLs on files and directories on the system. When a new file or subdirectory is created in a directory that has an ACL, the new file or subdirectory inherits all ACL Entries (ACEs) in the ACL that have been tagged with the appropriate inheritance flags.

When a file or directory is created as the result of an NFSv4 request, the ACL on the resulting file or directory depends on whether the file creation request includes an ACL or only standard UNIX file access permissions, and whether the parent directory has an ACL:

- If the request includes an ACL, that ACL is used.
- If the request includes only standard UNIX file access permissions but the parent directory has an ACL, the ACEs in the parent directory's ACL are inherited by the new file or directory as long as the ACEs have been tagged with the appropriate inheritance flags.

A parent ACL is inherited even if `-v4.0-acl` is set to `off`.

- If the request includes only standard UNIX file access permissions and the parent directory does not have an ACL, the client file mode is used to set standard UNIX file access permissions.
- If the request includes only standard UNIX file access permissions and the parent directory has a non-inheritable ACL, the new object is created only with mode bits.

If the `-chown-mode` parameter has been set to `restricted` with commands in the `vserver nfs` or `vserver export-policy` rule families, file ownership can be changed by the superuser only, even if the on-disk permissions set with NFSv4 ACLs allow a non-root user to change the file ownership. For more information, see the relevant man pages.

## Enable or disable modification of NFSv4 ACLs

When ONTAP receives a `chmod` command for a file or directory with an ACL, by default the ACL is retained and modified to reflect the mode bit change. You can disable the `-v4-acl-preserve` parameter to change the behavior if you want the ACL to be dropped instead.

### About this task

When using unified security style, this parameter also specifies whether NTFS file permissions are preserved or dropped when a client sends a `chmod`, `chgroup`, or `chown` command for a file or directory.

The default for this parameter is enabled.

### Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Perform one of the following actions:

| If you want to... | Enter the following command... |
|-------------------|--------------------------------|
| If you want to... | Enter the following command... |

|                                                                    |                                                                     |
|--------------------------------------------------------------------|---------------------------------------------------------------------|
| Enable retention and modification of existing NFSv4 ACLs (default) | vserver nfs modify -vserver vserver_name -v4-acl -preserve enabled  |
| Disable retention and drop NFSv4 ACLs when changing mode bits      | vserver nfs modify -vserver vserver_name -v4-acl -preserve disabled |

3. Return to the admin privilege level:

```
set -privilege admin
```

#### How ONTAP uses NFSv4 ACLs to determine whether it can delete a file

To determine whether it can delete a file, ONTAP uses a combination of the file's DELETE bit, and the containing directory's DELETE\_CHILD bit. For more information, see the NFS 4.1 RFC 5661.

#### Enable or disable NFSv4 ACLs

To enable or disable NFSv4 ACLs, you can modify the `-v4.0-acl` and `-v4.1-acl` options. These options are disabled by default.

#### About this task

The `-v4.0-acl` or `-v4.1-acl` option controls the setting and viewing of NFSv4 ACLs; it does not control enforcement of these ACLs for access checking.

#### Step

1. Perform one of the following actions:

| If you want to...    | Then...                                                                                                    |
|----------------------|------------------------------------------------------------------------------------------------------------|
| Enable NFSv4.0 ACLs  | Enter the following command:<br><br><pre>vserver nfs modify -vserver vserver_name -v4.0-acl enabled</pre>  |
| Disable NFSv4.0 ACLs | Enter the following command:<br><br><pre>vserver nfs modify -vserver vserver_name -v4.0-acl disabled</pre> |
| Enable NFSv4.1 ACLs  | Enter the following command:<br><br><pre>vserver nfs modify -vserver vserver_name -v4.1-acl enabled</pre>  |

|                             |                                                                                                            |
|-----------------------------|------------------------------------------------------------------------------------------------------------|
| <p>Disable NFSv4.1 ACLs</p> | <p>Enter the following command:</p> <pre>vserver nfs modify -vserver vserver_name -v4.1-acl disabled</pre> |
|-----------------------------|------------------------------------------------------------------------------------------------------------|

### Modify the maximum ACE limit for NFSv4 ACLs

You can modify the maximum number of allowed ACEs for each NFSv4 ACL by modifying the parameter `-v4-acl-max-aces`. By default, the limit is set to 400 ACEs for each ACL. Increasing this limit can help ensure successful migration of data with ACLs containing over 400 ACEs to storage systems running ONTAP.

#### About this task

Increasing this limit might impact performance for clients accessing files with NFSv4 ACLs.

#### Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Modify the maximum ACE limit for NFSv4 ACLs:

```
vserver nfs modify -v4-acl-max-aces max_ace_limit
```

The valid range of

`max_ace_limit` is 192 to 1024.

3. Return to the admin privilege level:

```
set -privilege admin
```

### Manage NFSv4 file delegations

#### Enable or disable NFSv4 read file delegations

To enable or disable NFSv4 read file delegations, you can modify the `-v4.0-read-delegation` or `-v4.1-read-delegation` option. By enabling read file delegations, you can eliminate much of the message overhead associated with the opening and closing of files.

#### About this task

By default, read file delegations are disabled.

The disadvantage of enabling read file delegations is that the server and its clients must recover delegations after the server reboots or restarts, a client reboots or restarts, or a network partition occurs.

#### Step

1. Perform one of the following actions:

| If you want to...                     | Then...                                                                                                             |
|---------------------------------------|---------------------------------------------------------------------------------------------------------------------|
| Enable NFSv4 read file delegations    | Enter the following command:<br><br>vserver nfs modify -vserver vserver_name -v4.0<br>-read-delegation enabled      |
| Enable NFSv4.1 read file delegations  | Enter the following command:<br><br>+<br>vserver nfs modify -vserver vserver_name -v4.1<br>-read-delegation enabled |
| Disable NFSv4 read file delegations   | Enter the following command:<br><br>vserver nfs modify -vserver vserver_name -v4.0<br>-read-delegation disabled     |
| Disable NFSv4.1 read file delegations | Enter the following command:<br><br>vserver nfs modify -vserver vserver_name -v4.1<br>-read-delegation disabled     |

## Result

The file delegation options take effect as soon as they are changed. There is no need to reboot or restart NFS.

### Enable or disable NFSv4 write file delegations

To enable or disable write file delegations, you can modify the -v4.0-write-delegation or -v4.1-write-delegation option. By enabling write file delegations, you can eliminate much of the message overhead associated with file and record locking in addition to opening and closing of files.

### About this task

By default, write file delegations are disabled.

The disadvantage of enabling write file delegations is that the server and its clients must perform additional tasks to recover delegations after the server reboots or restarts, a client reboots or restarts, or a network partition occurs.

### Step

1. Perform one of the following actions:

| If you want to...                   | Then...                                                                                                     |
|-------------------------------------|-------------------------------------------------------------------------------------------------------------|
| Enable NFSv4 write file delegations | Enter the following command: vserver nfs<br>modify -vserver vserver_name -v4.0<br>-write-delegation enabled |

| If you want to...                      | Then...                                                                                                |
|----------------------------------------|--------------------------------------------------------------------------------------------------------|
| Enable NFSv4.1 write file delegations  | Enter the following command: vserver nfs modify -vserver vserver_name -v4.1 -write-delegation enabled  |
| Disable NFSv4 write file delegations   | Enter the following command: vserver nfs modify -vserver vserver_name -v4.0 -write-delegation disabled |
| Disable NFSv4.1 write file delegations | Enter the following command: vserver nfs modify -vserver vserver_name -v4.1 -write-delegation disabled |

## Result

The file delegation options take effect as soon as they are changed. There is no need to reboot or restart NFS.

## Configure NFSv4 file and record locking

### About NFSv4 file and record locking

For NFSv4 clients, ONTAP supports the NFSv4 file-locking mechanism, maintaining the state of all file locks under a lease-based model.

[NetApp Technical Report 3580: NFSv4 Enhancements and Best Practices Guide Data ONTAP Implementation](#)

### Specify the NFSv4 locking lease period

To specify the NFSv4 locking lease period (that is, the time period in which ONTAP irrevocably grants a lock to a client), you can modify the `-v4-lease-seconds` option. Shorter lease periods speed up server recovery while longer lease periods are beneficial for servers handling a very large amount of clients.

### About this task

By default, this option is set to 30. The minimum value for this option is 10. The maximum value for this option is the locking grace period, which you can set with the `locking.lease_seconds` option.

### Steps

- Set the privilege level to advanced:

```
set -privilege advanced
```

- Enter the following command:

```
vserver nfs modify -vserver vserver_name -v4-lease-seconds number_of_seconds
```

- Return to the admin privilege level:

```
set -privilege admin
```

## Specify the NFSv4 locking grace period

To specify the NFSv4 locking grace period (that is, the time period in which clients attempt to reclaim their locking state from ONTAP during server recovery), you can modify the `-v4-grace-seconds` option.

### About this task

By default, this option is set to 45.

### Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Enter the following command:

```
vserver nfs modify -vserver vserver_name -v4-grace-seconds number_of_seconds
```

3. Return to the admin privilege level:

```
set -privilege admin
```

## How NFSv4 referrals work

When you enable NFSv4 referrals, ONTAP provides “intra-SVM” referrals to NFSv4 clients. Intra-SVM referral is when a cluster node receiving the NFSv4 request refers the NFSv4 client to another logical interface (LIF) on the storage virtual machine (SVM).

The NFSv4 client should access the path that received the referral at the target LIF from that point onward. The original cluster node provides such a referral when it determines that there exists a LIF in the SVM that is resident on the cluster node on which the data volume resides, thereby enabling the clients faster access to the data and avoiding extra cluster communication.

### Enable or disable NFSv4 referrals

You can enable NFSv4 referrals on storage virtual machines (SVMs) by enabling the options `-v4-fsid-change` and `-v4.0-referrals` or `-v4.1-referrals`. Enabling NFSv4 referrals can result in faster data access for NFSv4 clients that support this feature.

### What you'll need

If you want to enable NFS referrals, you must first disable parallel NFS. You cannot enable both at the same time.

### Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Perform one of the following actions:

| If you want to...         | Enter the command...                                                                                                               |
|---------------------------|------------------------------------------------------------------------------------------------------------------------------------|
| Enable NFSv4 referrals    | vserver nfs modify -vserver vserver_name -v4-fsid -change enabled vserver nfs modify -vserver vserver_name -v4.0-referrals enabled |
| Disable NFSv4 referrals   | vserver nfs modify -vserver vserver_name -v4.0 -referrals disabled                                                                 |
| Enable NFSv4.1 referrals  | vserver nfs modify -vserver vserver_name -v4-fsid -change enabled vserver nfs modify -vserver vserver_name -v4.1-referrals enabled |
| Disable NFSv4.1 referrals | vserver nfs modify -vserver vserver_name -v4.1 -referrals disabled                                                                 |

3. Return to the admin privilege level:

```
set -privilege admin
```

### Display NFS statistics

You can display NFS statistics for storage virtual machines (SVMs) on the storage system to monitor performance and diagnose issues.

#### Steps

1. Use the `statistics catalog object show` command to identify the NFS objects from which you can view data.

```
statistics catalog object show -object nfs*
```

2. Use the `statistics start` and optional `statistics stop` commands to collect a data sample from one or more objects.

3. Use the `statistics show` command to view the sample data.

#### Example: Monitoring NFSv3 performance

The following example shows performance data for the NFSv3 protocol.

The following command starts data collection for a new sample:

```
vsl:::> statistics start -object nfsv3 -sample-id nfs_sample
```

The following command shows data from the sample by specifying counters that show the number of successful read and write requests versus the total number of read and write requests:

```
vs1::> statistics show -sample-id nfs_sample -counter
read_total|write_total|read_success|write_success
```

Object: nfsv3

Instance: vs1

Start-time: 2/11/2013 15:38:29

End-time: 2/11/2013 15:38:41

Cluster: cluster1

| Counter       | Value   |
|---------------|---------|
| <hr/>         |         |
| read_success  | 40042   |
| read_total    | 40042   |
| write_success | 1492052 |
| write_total   | 1492052 |

## Display DNS statistics

You can display DNS statistics for storage virtual machines (SVMs) on the storage system to monitor performance and diagnose issues.

### Steps

1. Use the `statistics catalog object show` command to identify the DNS objects from which you can view data.

```
statistics catalog object show -object external_service_op*
```

2. Use the `statistics start` and `statistics stop` commands to collect a data sample from one or more objects.

3. Use the `statistics show` command to view the sample data.

### Monitoring DNS statistics

The following examples show performance data for DNS queries. The following commands start data collection for a new sample:

```
vs1::*> statistics start -object external_service_op -sample-id
dns_sample1
vs1::*> statistics start -object external_service_op_error -sample-id
dns_sample2
```

The following command displays data from the sample by specifying counters that display the number of DNS queries sent versus the number of DNS queries received, failed, or timed out:

```

vs1::*> statistics show -sample-id dns_sample1 -counter
num_requests_sent|num_responses_received|num_successful_responses|num_time
outs|num_request_failures|num_not_found_responses

Object: external_service_op
Instance: vs1:DNS:Query:10.72.219.109
Start-time: 3/8/2016 11:15:21
End-time: 3/8/2016 11:16:52
Elapsed-time: 91s
Scope: vs1

Counter Value

num_not_found_responses 0
num_request_failures 0
num_requests_sent 1
num_responses_received 1
num_successful_responses 1
num_timeouts 0
6 entries were displayed.

```

The following command displays data from the sample by specifying counters that display the number of times a specific error was received for a DNS query on the particular server:

```

vs1::*> statistics show -sample-id dns_sample2 -counter
server_ip_address|error_string|count

Object: external_service_op_error
Instance: vs1:DNS:Query:NXDOMAIN:10.72.219.109
Start-time: 3/8/2016 11:23:21
End-time: 3/8/2016 11:24:25
Elapsed-time: 64s
Scope: vs1

Counter Value

count 1
error_string NXDOMAIN
server_ip_address 10.72.219.109
3 entries were displayed.

```

## Related information

## Display NIS statistics

You can display NIS statistics for storage virtual machines (SVMs) on the storage system to monitor performance and diagnose issues.

### Steps

1. Use the `statistics catalog object show` command to identify the NIS objects from which you can view data.

```
statistics catalog object show -object external_service_op*
```

2. Use the `statistics start` and `statistics stop` commands to collect a data sample from one or more objects.
3. Use the `statistics show` command to view the sample data.

### Monitoring NIS statistics

The following examples display performance data for NIS queries. The following commands start data collection for a new sample:

```
vs1::*: > statistics start -object external_service_op -sample-id
nis_sample1
vs1::*: > statistics start -object external_service_op_error -sample-id
nis_sample2
```

The following command displays data from the sample by specifying counters that show the number of NIS queries sent versus the number of NIS queries received, failed, or timed out:

```

vs1::*> statistics show -sample-id nis_sample1 -counter
instance|num_requests_sent|num_responses_received|num_successful_responses
|num_timeouts|num_request_failures|num_not_found_responses

Object: external_service_op
Instance: vs1:NIS:Query:10.227.13.221
Start-time: 3/8/2016 11:27:39
End-time: 3/8/2016 11:27:56
Elapsed-time: 17s
Scope: vs1

Counter Value

num_not_found_responses 0
num_request_failures 1
num_requests_sent 2
num_responses_received 1
num_successful_responses 1
num_timeouts 0
6 entries were displayed.

```

The following command displays data from the sample by specifying counters that show the number of times a specific error was received for a NIS query on the particular server:

```

vs1::*> statistics show -sample-id nis_sample2 -counter
server_ip_address|error_string|count

Object: external_service_op_error
Instance: vs1:NIS:Query:YP_NOTFOUND:10.227.13.221
Start-time: 3/8/2016 11:33:05
End-time: 3/8/2016 11:33:10
Elapsed-time: 5s
Scope: vs1

Counter Value

count 1
error_string YP_NOTFOUND
server_ip_address 10.227.13.221
3 entries were displayed.

```

## Support for VMware vStorage over NFS

ONTAP supports certain VMware vStorage APIs for Array Integration (VAAI) features in an NFS environment.

### Supported features

The following features are supported:

- Copy offload

Enables an ESXi host to copy virtual machines or virtual machine disks (VMDKs) directly between the source and destination data store location without involving the host. This conserves ESXi host CPU cycles and network bandwidth. Copy offload preserves space efficiency if the source volume is sparse.

- Space reservation

Guarantees storage space for a VMDK file by reserving space for it.

### Limitations

VMware vStorage over NFS has the following limitations:

- Copy offload operations can fail in the following scenarios:
  - While running wafliron on the source or destination volume because it temporarily takes the volume offline
  - While moving either the source or destination volume
  - While moving either the source or destination LIF
  - While performing takeover or giveback operations
  - While performing switchover or switchback operations
- Server-side copy can fail due to file handle format differences in the following scenario:

You attempt to copy data from SVMs that have currently or had previously exported qtrees to SVMs that have never had exported qtrees. To work around this limitation, you can export at least one qtree on the destination SVM.

### Related information

[What VAAI offloaded operations are supported by Data ONTAP?](#)

### Enable or disable VMware vStorage over NFS

You can enable or disable support for VMware vStorage over NFS on storage virtual machines (SVMs) by using the `vserver nfs modify` command.

### About this task

By default, support for VMware vStorage over NFS is disabled.

### Steps

1. Display the current vStorage support status for SVMs:

```
vserver nfs show -vserver vserver_name -instance
```

## 2. Perform one of the following actions:

| If you want to...               | Enter the following command...                              |
|---------------------------------|-------------------------------------------------------------|
| Enable VMware vStorage support  | vserver nfs modify -vserver vserver_name -vstorage enabled  |
| Disable VMware vStorage support | vserver nfs modify -vserver vserver_name -vstorage disabled |

## After you finish

You must install the NFS Plug-in for VMware VAAI before you can use this functionality. For more information, see *Installing the NetApp NFS Plug-in for VMware VAAI*.

## Related information

[NetApp Documentation: NetApp NFS Plug-in for VMware VAAI](#)

## Enable or disable rquota support

ONTAP supports the remote quota protocol version 1 (rquota v1). The rquota protocol enables NFS clients to obtain quota information for users from a remote machine. You can enable rquota on storage virtual machines (SVMs) by using the `vserver nfs modify` command.

## About this task

By default, rquota is disabled.

## Step

### 1. Perform one of the following actions:

| If you want to...               | Enter the following command...                           |
|---------------------------------|----------------------------------------------------------|
| Enable rquota support for SVMs  | vserver nfs modify -vserver vserver_name -rquota enable  |
| Disable rquota support for SVMs | vserver nfs modify -vserver vserver_name -rquota disable |

For more information about quotas, see [Logical storage management](#).

## NFSv3 and NFSv4 performance improvement by modifying the TCP transfer size

You can improve the performance of NFSv3 and NFSv4 clients connecting to storage systems over a high-latency network by modifying the TCP maximum transfer size.

When clients access storage systems over a high-latency network, such as a wide area network (WAN) or

metro area network (MAN) with a latency over 10 milliseconds, you might be able to improve the connection performance by modifying the TCP maximum transfer size. Clients accessing storage systems in a low-latency network, such as a local area network (LAN), can expect little to no benefit from modifying these parameters. If the throughput improvement does not outweigh the latency impact, you should not use these parameters.

To determine whether your storage environment would benefit from modifying these parameters, you should first conduct a comprehensive performance evaluation of a poorly performing NFS client. Review whether the low performance is because of excessive round trip latency and small request on the client. Under these conditions, the client and server cannot fully use the available bandwidth because they spend the majority of their duty cycles waiting for small requests and responses to be transmitted over the connection.

By increasing the NFSv3 and NFSv4 request size, the client and server can use the available bandwidth more effectively to move more data per unit time; therefore, increasing the overall efficiency of the connection.

Keep in mind that the configuration between the storage system and the client might vary. The storage system and the client supports maximum size of 1 MB for transfer operations. However, if you configure the storage system to support 1 MB maximum transfer size but the client only supports 64 KB, then the mount transfer size is limited to 64 KB or less.

Before modifying these parameters, you must be aware that it results in additional memory consumption on the storage system for the period of time necessary to assemble and transmit a large response. The more high-latency connections to the storage system, the higher the additional memory consumption. Storage systems with high memory capacity might experience very little effect from this change. Storage systems with low memory capacity might experience noticeable performance degradation.

The successful use of these parameter relies on the ability to retrieve data from multiple nodes of a cluster. The inherent latency of the cluster network might increase the overall latency of the response. Overall latency tends to increase when using these parameters. As a result, latency sensitive workloads might show negative impact.

### Modify the NFSv3 and NFSv4 TCP maximum transfer size

You can modify the `-tcp-max-xfer-size` option to configure maximum transfer sizes for all TCP connections using the NFSv3 and NFSv4.x protocols.

#### About this task

You can modify these options individually for each storage virtual machine (SVM).

Beginning with ONTAP 9, the `v3-tcp-max-read-size` and `v3-tcp-max-write-size` options are obsolete. You must use the `-tcp-max-xfer-size` option instead.

#### Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Perform one of the following actions:

| If you want to...                                   | Enter the command...                                                                         |
|-----------------------------------------------------|----------------------------------------------------------------------------------------------|
| Modify the NFSv3 or NFSv4 TCP maximum transfer size | <pre>vserver nfs modify -vserver vserver_name -tcp-max-xfer-size integer_max_xfer_size</pre> |

| Option             | Range                 | Default     |
|--------------------|-----------------------|-------------|
| -tcp-max-xfer-size | 8192 to 1048576 bytes | 65536 bytes |

The maximum transfer size that you enter must be a multiple of 4 KB (4096 bytes). Requests that are not properly aligned negatively affect performance.

3. Use the `vserver nfs show -fields tcp-max-xfer-size` command to verify the changes.
4. If any clients use static mounts, unmount and remount for the new parameter size to take effect.

#### Example

The following command sets the NFSv3 and NFSv4.x TCP maximum transfer size to 1048576 bytes on the SVM named vs1:

```
vs1::> vserver nfs modify -vserver vs1 -tcp-max-xfer-size 1048576
```

#### Configure the number of group IDs allowed for NFS users

By default, ONTAP supports up to 32 group IDs when handling NFS user credentials using Kerberos (RPCSEC\_GSS) authentication. When using AUTH\_SYS authentication, the default maximum number of group IDs is 16, as defined in RFC 5531. You can increase the maximum up to 1,024 if you have users who are members of more than the default number of groups.

#### About this task

If a user has more than the default number of group IDs in their credentials, the remaining group IDs are truncated and the user might receive errors when attempting to access files from the storage system. You should set the maximum number of groups, per SVM, to a number that represents the maximum groups in your environment.

The following table shows the two parameters of the `vserver nfs modify` command that determine the maximum number of group IDs in three sample configurations:

| Parameters                             | Settings | Resulting group IDs limit       |
|----------------------------------------|----------|---------------------------------|
| <code>-extended-groups-limit</code>    | 32       | RPCSEC_GSS: 32                  |
| <code>-auth-sys-extended-groups</code> | disabled | AUTH_SYS: 16                    |
|                                        |          | These are the default settings. |
| <code>-extended-groups-limit</code>    | 256      | RPCSEC_GSS: 256                 |
| <code>-auth-sys-extended-groups</code> | disabled | AUTH_SYS: 16                    |

|                           |         |                 |
|---------------------------|---------|-----------------|
| -extended-groups-limit    | 512     | RPCSEC_GSS: 512 |
| -auth-sys-extended-groups | enabled | AUTH_SYS: 512   |

Some older NFS clients might not be compatible with AUTH\_SYS extended groups.

## Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Perform the desired action:

| If you want to set the maximum number of allowed auxiliary groups...  | Enter the command...                                                                                                  |
|-----------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------|
| Only for RPCSEC_GSS and leave AUTH_SYS set to the default value of 16 | vserver nfs modify -vserver<br>vserver_name -extended-groups-limit<br>{32-1024} -auth-sys-extended-groups<br>disabled |
| For both RPCSEC_GSS and AUTH_SYS                                      | vserver nfs modify -vserver<br>vserver_name -extended-groups-limit<br>{32-1024} -auth-sys-extended-groups<br>enabled  |

3. Verify the -extended-groups-limit value and verify whether AUTH\_SYS is using extended groups:

```
vserver nfs show -vserver vserver_name -fields auth-sys-extended-groups,extended-groups-limit
```

4. Return to the admin privilege level:

```
set -privilege admin
```

## Example

The following example enables extended groups for AUTH\_SYS authentication and sets the maximum number of extended groups to 512 for both AUTH\_SYS and RPCSEC\_GSS authentication. These changes are made only for clients who access the SVM named vs1:

```

vs1::> set -privilege advanced
Warning: These advanced commands are potentially dangerous; use
 them only when directed to do so by NetApp personnel.
Do you want to continue? {y|n}: y

vs1::*> vserver nfs modify -vserver vs1 -auth-sys-extended-groups enabled
-extended-groups-limit 512

vs1::*> vserver nfs show -vserver vs1 -fields auth-sys-extended-
groups,extended-groups-limit
vserver auth-sys-extended-groups extended-groups-limit

vs1 enabled 512

vs1::*> set -privilege admin

```

## Control root user access to NTFS security-style data

You can configure ONTAP to allow NFS clients access to NTFS security-style data and NTFS clients to access NFS security-style data. When using NTFS security style on an NFS data store, you must decide how to treat access by the root user and configure the storage virtual machine (SVM) accordingly.

### About this task

When a root user accesses NTFS security-style data, you have two options:

- Map the root user to a Windows user like any other NFS user and manage access according to NTFS ACLs.
- Ignore NTFS ACLs and provide full access to root.

### Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Perform the desired action:

| If you want the root user to... | Enter the command...                                                       |
|---------------------------------|----------------------------------------------------------------------------|
| Be mapped to a Windows user     | vserver nfs modify -vserver vserver_name -ignore -nt-acl-for-root disabled |
| Bypass the NT ACL check         | vserver nfs modify -vserver vserver_name -ignore -nt-acl-for-root enabled  |

By default, this parameter is disabled.

If this parameter is enabled but there is no name mapping for the root user, ONTAP uses a default SMB administrator credential for auditing.

3. Return to the admin privilege level:

```
set -privilege admin
```

## Supported NFS versions and clients

### Overview of supported NFS versions and clients

Before you can use NFS in your network, you need to know which NFS versions and clients ONTAP supports.

This table notes when major and minor NFS protocol versions are supported by default in ONTAP. Support by default does not indicate that this is the earliest version of ONTAP supporting that NFS protocol.

| Version | Enabled by default              |
|---------|---------------------------------|
| NFSv3   | Yes                             |
| NFSv4.0 | Yes, beginning with ONTAP 9.9.1 |
| NFSv4.1 | Yes, beginning with ONTAP 9.9.1 |
| NFSv4.2 | Yes, beginning with ONTAP 9.9.1 |
| pNFS    | No                              |

For the latest information about which NFS clients ONTAP supports, see the Interoperability Matrix.

[NetApp Interoperability Matrix Tool](#)

### NFSv4.0 functionality supported by ONTAP

ONTAP supports all the mandatory functionality in NFSv4.0 except the SPKM3 and LIPKEY security mechanisms.

The following NFSV4 functionality is supported:

- **COMPOUND**

Allows a client to request multiple file operations in a single remote procedure call (RPC) request.

- **File delegation**

Allows the server to delegate file control to some types of clients for read and write access.

- **Pseudo-fs**

Used by NFSv4 servers to determine mount points on the storage system. There is no mount protocol in

NFSv4.

- **Locking**

Lease-based. There are no separate Network Lock Manager (NLM) or Network Status Monitor (NSM) protocols in NFSv4.

For more information about the NFSv4.0 protocol, see RFC 3530.

### Limitations of ONTAP support for NFSv4

You should be aware of several limitations of ONTAP support for NFSv4.

- The delegation feature is not supported by every client type.
- In ONTAP 9.4 and earlier releases, names with non-ASCII characters on volumes other than UTF8 volumes are rejected by the storage system.

In ONTAP 9.5 and later releases, volumes created with the utf8mb4 language setting and mounted using NFS v4 are no longer subject to this restriction.

- All file handles are persistent; the server does not give volatile file handles.
- Migration and replication are not supported.
- NFSv4 clients are not supported with read-only load-sharing mirrors.

ONTAP routes NFSv4 clients to the source of the load-sharing mirror for direct read and write access.

- Named attributes are not supported.
- All recommended attributes are supported, except for the following:

- archive
- hidden
- homogeneous
- mimetype
- quota\_avail\_hard
- quota\_avail\_soft
- quota\_used
- system
- time\_backup

Although it does not support the quota\* attributes, ONTAP does support user and group quotas through the RQUOTA side band protocol.

### ONTAP support for NFSv4.1

Beginning with ONTAP 9.8, nconnect functionality is available by default when NFSv4.1 is enabled.

Earlier NFS client implementations use only a single TCP connection with a mount. In ONTAP, a single TCP connection can become a bottleneck with increasing IOPS. However, an nconnect-enabled client can have multiple TCP connections (up to 16) associated with a single NFS mount. Such an NFS client multiplexes file operations onto multiple TCP connections in a round-robin fashion and thus obtains higher throughput from the available network bandwidth. Nconnect is recommended for NFSv3 and NFSv4.1 mounts only.

See your NFS client documentation to confirm whether nconnect is supported in your client version.

NFSv4.1 is enabled by default in ONTAP 9.9.1 and later. In earlier releases, you can enable it by specifying the `-v4.1` option and setting it to `enabled` when creating an NFS server on the storage virtual machine (SVM).

ONTAP does not support NFSv4.1 directory and file level delegations.

## ONTAP support for NFSv4.2

Beginning with ONTAP 9.8, the NFSv4.2 protocol is supported to allow access for NFSv4.2-enabled clients.

NFSv4.2 is enabled by default in ONTAP 9.9.1 and later. In ONTAP 9.8, you can enable v4.2 by specifying the `-v4.1` option and setting it to `enabled` when creating an NFS server on the storage virtual machine (SVM). Enabling NFSv4.1 also enables clients to use the NFSv4.1 features while mounted as v4.2.

The following NFSv4.2 optional features are supported:

| Feature                                     | Supported beginning with ... |
|---------------------------------------------|------------------------------|
| Mandatory Access Control (MAC) labelled NFS | ONTAP 9.9.1                  |
| NFS extended attributes                     | ONTAP 9.12.1                 |

Additional NFSv4.2 optional features will be added in a later ONTAP release.

## Enable NFS v4.2 security labels

Beginning with ONTAP 9.9.1, NFS security labels can be enabled. They are disabled by default.

With NFS v4.2 security labels, ONTAP NFS servers are Mandatory Access Control (MAC) aware, storing and retrieving `sec_label` attributes sent by clients.

For more information, see [RFC 7240](#)

Beginning with ONTAP 9.12.1, NFS v4.2 security labels are supported for NDMP dump operations. If security labels are encountered on files or directories in earlier releases, the dump fails.

## Steps

1. Change the privilege setting to advanced:

```
set -privilege advanced
```

2. Enable security labels:

```
vserver nfs modify -vserver svm_name -v4.2-seclabel enabled
```

## **Enable NFS extended attributes**

Beginning with ONTAP 9.12.1, NFS extended attributes (xattr) are enabled by default.

Extended attributes are standard NFS attributes defined by [RFC 8276](#) and enabled in modern NFS clients. They can be used to attach user-defined metadata to file system objects, and are of interest in advanced security deployments.

NFS extended attributes are not currently supported for NDMP dump operations. If extended attributes are encountered on files or directories, the dump proceeds but does not back up the extended attributes on those files or directories.

If you need to disable extended attributes, use the `vserver nfs modify -v4.2-xattrs disabled` command.

## **ONTAP support for parallel NFS**

ONTAP supports parallel NFS (pNFS). The pNFS protocol offers performance improvements by giving clients direct access to the data of a set of files distributed across multiple nodes of a cluster. It helps clients locate the optimal path to a volume.

## **Use of hard mounts**

When troubleshooting mounting problems, you need to be sure that you are using the correct mount type. NFS supports two mount types: soft mounts and hard mounts. You should use only hard mounts for reliability reasons.

You should not use soft mounts, especially when there is a possibility of frequent NFS timeouts. Race conditions can occur as a result of these timeouts, which can lead to data corruption.

## **NFS and SMB file and directory naming dependencies**

### **Overview of NFS and SMB file and directory naming dependencies**

File and directory naming conventions depend on both the network clients' operating systems and the file-sharing protocols, in addition to language settings on the ONTAP cluster and clients.

The operating system and the file-sharing protocols determine the following:

- Characters a file name can use
- Case-sensitivity of a file name

ONTAP supports multi-byte characters in file, directory, and qtree names, depending on the ONTAP release.

### **Characters a file or directory name can use**

If you are accessing a file or directory from clients with different operating systems, you should use characters that are valid in both operating systems.

For example, if you use UNIX to create a file or directory, do not use a colon (:) in the name because the colon is not allowed in MS-DOS file or directory names. Because restrictions on valid characters vary from one

operating system to another, see the documentation for your client operating system for more information about prohibited characters.

### Case-sensitivity of file and directory names in a multiprotocol environment

File and directory names are case-sensitive for NFS clients and case-insensitive but case-preserving for SMB clients. You must understand what the implications are in a multiprotocol environment and the actions you might need to take when specifying the path while creating SMB shares and when accessing data within the shares.

If an SMB client creates a directory named testdir, both SMB and NFS clients display the file name as testdir. However, if an SMB user later tries to create a directory name TESTDIR, the name is not allowed because, to the SMB client, that name currently exists. If an NFS user later creates a directory named TESTDIR, NFS and SMB clients display the directory name differently, as follows:

- On NFS clients, you see both directory names as they were created, for example testdir and TESTDIR, because directory names are case-sensitive.
- SMB clients use the 8.3 names to distinguish between the two directories. One directory has the base file name. Additional directories are assigned an 8.3 file name.
  - On SMB clients, you see testdir and TESTDI~1.
  - ONTAP creates the TESTDI~1 directory name to differentiate the two directories.

In this case, you must use the 8.3 name when specifying a share path while creating or modifying a share on a storage virtual machine (SVM).

Similarly for files, if an SMB client creates test.txt, both SMB and NFS clients display the file name as text.txt. However, if an SMB user later tries to create Test.txt, the name is not allowed because, to the SMB client, that name currently exists. If an NFS user later creates a file named Test.txt, NFS and SMB clients display the file name differently, as follows:

- On NFS clients, you see both file names as they were created, test.txt and Test.txt, because file names are case-sensitive.
- SMB clients use the 8.3 names to distinguish between the two files. One file has the base file name. Additional files are assigned an 8.3 file name.
  - On SMB clients, you see test.txt and TEST~1.TXT.
  - ONTAP creates the TEST~1.TXT file name to differentiate the two files.

If you have enabled or modified character mapping using the Vserver CIFS character-mapping commands, a normally case-insensitive Windows lookup becomes case-sensitive.

### How ONTAP creates file and directory names

ONTAP creates and maintains two names for files or directories in any directory that has access from an SMB client: the original long name and a name in 8.3 format.

For file or directory names that exceed the eight character name or the three character extension limit (for files), ONTAP generates an 8.3-format name as follows:

- It truncates the original file or directory name to six characters, if the name exceeds six characters.
- It appends a tilde (~) and a number, one through five, to file or directory names that are no longer unique after being truncated.

If it runs out of numbers because there are more than five similar names, it creates a unique name that bears no relation to the original name.

- In the case of files, it truncates the file name extension to three characters.

For example, if an NFS client creates a file named `specifications.html`, the 8.3 format file name created by ONTAP is `specif~1.htm`. If this name already exists, ONTAP uses a different number at the end of the file name. For example, if an NFS client then creates another file named `specifications_new.html`, the 8.3 format of `specifications_new.html` is `specif~2.htm`.

### How ONTAP handles multi-byte file, directory, and qtree names

Beginning with ONTAP 9.5, support for 4-byte UTF-8 encoded names enables the creation and display of file, directory, and tree names that include Unicode supplementary characters outside the Basic Multilingual Plane (BMP). In earlier releases, these supplementary characters did not display correctly in multiprotocol environments.

To enable support for 4-byte UTF-8 encoded names, a new `utf8mb4` language code is available for the `vserver` and `volume` command families.

- You must create a new volume in one of the following ways:
- Setting the `volume -language` option explicitly:

```
volume create -language utf8mb4 {...}
```

- Inheriting the `volume -language` option from an SVM that has been created with or modified for the `option`:

```
vserver [create|modify] -language utf8mb4 {...}``volume create {...}
```

- You cannot modify existing volumes for `utf8mb4` support; you must create a new `utf8mb4`-ready volume, and then migrate the data using client-based copy tools.

You can update SVMs for `utf8mb4` support, but existing volumes retain their original language codes.

LUN names with 4-byte UTF-8 characters are not currently supported.

- Unicode character data is typically represented in Windows file systems applications using the 16-bit Unicode Transformation Format (UTF-16) and in NFS file systems using the 8-bit Unicode Transformation Format (UTF-8).

In releases prior to ONTAP 9.5, names including UTF-16 supplementary characters that were created by Windows clients were correctly displayed to other Windows clients but were not translated correctly to UTF-8 for NFS clients. Similarly, names with UTF-8 supplementary characters by created NFS clients were not translated correctly to UTF-16 for Windows clients.

- When you create file names on systems running ONTAP 9.4 or earlier that contain valid or invalid supplementary characters, ONTAP rejects the file name and returns an invalid file name error.

To avoid this issue, use only BMP characters in file names and avoid using supplementary characters, or upgrade to ONTAP 9.5 or later.

Unicode characters are allowed in qtree names.

- You can use either the `volume qtree` command family or System Manager to set or modify qtree names.
- qtree names can include multi-byte characters in Unicode format, such as Japanese and Chinese characters.
- In releases before ONTAP 9.5, only BMP characters (that is, those that could be represented in 3 bytes) were supported.

In releases before ONTAP 9.5, the junction-path of the qtree's parent volume can contain qtree and directory names with Unicode characters. The `volume show` command displays these names correctly when the parent volume has a UTF-8 language setting. However, if the parent volume language is not one of the UTF-8 language settings, some parts of the junction-path are displayed using a numeric NFS alternate name.

- In 9.5 and later releases, 4-byte characters are supported in qtree names, provided that the qtree is in a volume enabled for `utf8mb4`.

## Configure character mapping for SMB file name translation on volumes

NFS clients can create file names that contain characters that are not valid for SMB clients and certain Windows applications. You can configure character mapping for file name translation on volumes to allow SMB clients to access files with NFS names that would otherwise not be valid.

### About this task

When files created by NFS clients are accessed by SMB clients, ONTAP looks at the name of the file. If the name is not a valid SMB file name (for example, if it has an embedded colon ":" character), ONTAP returns the 8.3 file name that is maintained for each file. However, this causes problems for applications that encode important information into long file names.

Therefore, if you are sharing a file between clients on different operating systems, you should use characters in the file names that are valid in both operating systems.

However, if you have NFS clients that create file names containing characters that are not valid file names for SMB clients, you can define a map that converts the invalid NFS characters into Unicode characters that both SMB and certain Windows applications accept. For example, this functionality supports the CATIA MCAD and Mathematica applications as well as other applications that have this requirement.

You can configure character mapping on a volume-by-volume basis.

You must keep the following in mind when configuring character mapping on a volume:

- Character mapping is not applied across junction points.

You must explicitly configure character mapping for each junction volume.

- You must make sure that the Unicode characters that are used to represent invalid or illegal characters are characters that do not normally appear in file names; otherwise, unwanted mappings occur.

For example, if you try to map a colon (:) to a hyphen (-) but the hyphen (-) was used in the file name correctly, a Windows client trying to access a file named “a-b” would have its request mapped to the NFS name of “a:b” (not the desired outcome).

- After applying character mapping, if the mapping still contains an invalid Windows character, ONTAP falls back to Windows 8.3 file names.
- In FPolicy notifications, NAS audit logs, and security trace messages, the mapped file names are shown.
- When a SnapMirror relation of type DP is created, the source volume’s character mapping is not replicated on the destination DP volume.
- Case sensitivity: Because the mapped Windows names turn into NFS names, the lookup of the names follows NFS semantics. That includes the fact that NFS lookups are case-sensitive. This means that the applications accessing mapped shares must not rely on Windows case-insensitive behavior. However, the 8.3 name is available, and that is case-insensitive.
- Partial or invalid mappings: After mapping a name to return to clients doing directory enumeration ("dir"), the resulting Unicode name is checked for Windows validity. If that name still has invalid characters in it, or if it is otherwise invalid for Windows (e.g. it ends in "." or blank) the 8.3 name is returned instead of the invalid name.

## Step

1. Configure character mapping:

```
vserver cifs character-mapping create -vserver vserver_name -volume
volume_name -mapping mapping_text, ...
```

The mapping consists of a list of source-target character pairs separated by “：“. The characters are Unicode characters entered using hexadecimal digits. For example: 3C:E03C.

The first value of each `mapping_text` pair that is separated by a colon is the hexadecimal value of the NFS character you want to translate, and the second value is the Unicode value that SMB uses. The mapping pairs must be unique (a one-to-one mapping should exist).

- Source mapping

The following table shows the permissible Unicode character set for source mapping:

| Unicode character | Printed character | Description                     |
|-------------------|-------------------|---------------------------------|
| 0x01-0x19         | Not applicable    | Non-printing control characters |
| 0x5C              | \                 | Backslash                       |
| 0x3A              | :                 | Colon                           |
| 0x2A              | *                 | Asterisk                        |
| 0x3F              | ?                 | Question mark                   |
| 0x22              | "                 | Quotation mark                  |

|      |   |                 |
|------|---|-----------------|
| 0x3C | < | Less than       |
| 0x3E | > | Greater than    |
| 0x7C |   | Vertical line   |
| 0xB1 | ± | Plus-minus sign |

- Target mapping

You can specify target characters in the “Private Use Area” of Unicode in the following range: U+E0000...U+F8FF.

### Example

The following command creates a character mapping for a volume named “data” on storage virtual machine (SVM) vs1:

```
cluster1::> vserver cifs character-mapping create -volume data -mapping
3c:e17c,3e:f17d,2a:f745
cluster1::> vserver cifs character-mapping show

Vserver Volume Name Character Mapping
----- ----- -----
vs1 data 3c:e17c, 3e:f17d, 2a:f745
```

### Commands for managing character mappings for SMB file name translation

You can manage character mapping by creating, modifying, displaying information about, or deleting file character mappings used for SMB file name translation on FlexVol volumes.

| If you want to...                                 | Use this command...                   |
|---------------------------------------------------|---------------------------------------|
| Create new file character mappings                | vserver cifs character-mapping create |
| Display information about file character mappings | vserver cifs character-mapping show   |
| Modify existing file character mappings           | vserver cifs character-mapping modify |
| Delete file character mappings                    | vserver cifs character-mapping delete |

For more information, see the man page for each command.

# Manage NFS over RDMA

## NFS over RDMA

NFS over RDMA utilizes RDMA adapters, allowing data to be copied directly between storage system memory and host system memory, circumventing CPU interruptions and overhead.

NFS over RDMA configurations are designed for customers with latency sensitive or high-bandwidth workloads such as machine learning and analytics. NVIDIA has extended NFS over RDMA to enable GPU Direct Storage (GDS). GDS further accelerates GPU-enabled workloads by bypassing the CPU and main memory altogether, using RDMA to transfer data between the storage system and GPU memory directly.

NFS over RDMA is supported beginning with ONTAP 9.10.1. NFS over RDMA configurations are only supported for the NFSv4.0 protocol when used with the Mellanox CX-5 or CX-6 adapter, which provides support for RDMA using version 2 of the RoCE protocol. GDS is only supported using NVIDIA Tesla- and Ampere-family GPUs with Mellanox NIC cards and MOFED software. NFS over RDMA support is limited to node-local traffic only. Standard FlexVols or FlexGroups where all constituents are on the same node are supported and must be accessed from a LIF on the same node. NFS mount sizes higher than 64k result in unstable performance with NFS over RDMA configurations.

### Requirements

- Storage systems must be running ONTAP 9.10.1 or later
  - You can configure NFS over RDMA with System Manager beginning with ONTAP 9.12.1. In ONTAP 9.10.1 and 9.11.1, you need to use the CLI to configure NFS over RDMA.
- Both nodes in the HA pair must be the same version.
- Storage system controllers must have RDMA support (currently A400, A700, and A800).
- Storage appliance configured with RDMA-supported hardware (e.g. Mellanox CX-5 or CX-6).
- Data LIFs must be configured to support RDMA.
- Clients must be using Mellanox RDMA-capable NIC cards and Mellanox OFED (MOFED) network software.

Interface groups are not supported with NFS over RDMA.

### What's next

- [Configure NICs for NFS over RDMA](#)
- [Configure LIFs for NFS over RDMA](#)
- [NFS settings for NFS over RDMA](#)

### Related information

- [RDMA](#)
- [RFC 7530: NFS Version 4 Protocol](#)
- [RFC 8166: Remote Direct Memory Access Transport for Remote Procedure Call Version 1](#)
- [RFC 8167: Bidirectional Remote Procedure Call on RPC-over-RDMA Transports](#)
- [RFC 8267: NFS Upper-Layer Binding to RPC-over-RDMA version 1](#)

## Configure NICs for NFS over RDMA

NFS over RDMA requires NIC configuration for both the client system and storage platform.

### Storage platform configuration

An X1148 RDMA adapter needs to be installed on the server. If you are using an HA configuration, you must have a corresponding X1148 adapter on the failover partner so RDMA service can continue during failover. The NIC must be ROCE capable.

Beginning with ONTAP 9.10.1, you can view a list of RDMA offload protocols with the command:

```
network port show -rdma-protocols roce
```

### Client system configuration

Clients must be using Mellanox RDMA-capable NIC cards (e.g. X1148) and Mellanox OFED network software. Consult Mellanox documentation for supported models and versions. Although the client and server can be directly connected, the use of switches is recommended due to improved failover performance with a switch.

The client, server, and any switches, and all ports on switches must be configured using Jumbo frames. Also ensure that priority flow-control is in effect on any switches.

Once this configuration is confirmed, you can mount the NFS.

## System Manager

You must be using ONTAP 9.12.1 or later to configure network interfaces with NFS over RDMA using System Manager.

### Steps

1. Check if RDMA is supported. Navigate to **Network > Ethernet Ports** and select the appropriate node in the group view. When you expand the node, look at the **RDMA protocols** field for a given port: the value **RoCE** denotes RDMA is supported; a dash (-) indicates it is not supported.
2. To add a VLAN, select **+ VLAN**. Select the appropriate node. In the **Port** dropdown menu, the available ports will display the text **RoCE Enabled** if they support RDMA; no text will be displayed if they do not support RDMA.
3. Follow the workflow in [Enable NAS storage for Linux servers using NFS](#) to configure a new NFS server.

When adding network interfaces, you will have the option to select **Use RoCE ports**. Select this option for any network interfaces that you want to use NFS over RDMA.

### CLI

1. Check if RDMA access is enabled on the NFS server with the command:

```
vserver nfs show-vserver SVM_name
```

By default, `-rdma` should be enabled. If it is not, enable RDMA access on the NFS server:

```
vserver nfs modify -vserver SVM_name -rdma enabled
```

2. Mount the client via NFSv4.0 over RDMA:

- a. The input for the `proto` parameter depends on the server IP protocol version. If it is IPv4, use `proto=rdma`. If it is IPv6, use `proto=rdma6`.
- b. Specify the NFS target port as `port=20049` instead of the standard port 2049:

```
mount -o vers=4,minorversion=0,proto=rdma,port=20049 Server_IP_address
:/volume_path mount_point
```

3. **OPTIONAL:** If you need to unmount the client, run the command `umount mount_path`

### More information

- [Create an NFS server](#)
- [Enable NAS storage for Linux servers using NFS](#)

## Configure LIFs for NFS over RDMA

To utilize NFS over RDMA, you must configure your LIFs (network interface) to be RDMA compatible. Both the LIF and its failover pair must be capable of supporting RDMA.

## Create a new LIF

### System Manager

You must be running ONTAP 9.12.1 or later to create a network interface for NFS over RDMA with System Manager.

#### Steps

1. Select **Network > Overview > Network Interfaces**.
2. Select  **Add**.
3. When you select **NFS,SMB/CIFS,S3**, you will have the option to **Use RoCE ports**. Select the checkbox for **Use RoCE ports**.
4. Select the storage VM and home node. Assign a name. Enter the IP address and subnet mask.
5. Once you enter the IP address and subnet mask, System Manager will filter the list of broadcast domains to those that have RoCE capable ports. Select a broadcast domain. You can optionally add a gateway.
6. Select **Save**.

### CLI

#### Steps

1. Create a LIF:

```
network interface create -vserver SVM_name -lif lif_name -service-policy service_policy_name -home-node node_name -home-port port_name {-address IP_address -netmask netmask_value | -subnet-name subnet_name} -firewall -policy policy_name -auto-revert {true|false} -rdma-protocols roce
```

- The service policy must be either default-data-files or a custom policy that includes the data-nfs network interface service.
- The **-rdma-protocols** parameter accepts a list, which is by default empty. When **roce** is added as a value, the LIF can only be configured on ports supporting RoCE offload, affecting both LIF migration and failover.

## Modify a LIF

## System Manager

You must be running ONTAP 9.12.1 or later to create a network interface for NFS over RDMA with System Manager.

### Steps

1. Select **Network > Overview > Network Interfaces**.
2. Select  **Edit** beside the network interface you want to change.
3. Check **Use RoCE Ports** to enable NFS over RDMA or uncheck the box to disable it. If the network interface is on a RoCE capable port, you will see a checkbox next to **Use RoCE ports**.
4. Modify the other settings as needed.
5. Select **Save** to confirm your changes.

### CLI

1. You can check the status of your LIFs with the `network interface show` command. The service policy must include the data-nfs network interface service. The `-rdma-protocols` list should include `roce`. If either of these conditions are untrue, modify the LIF.
2. To modify the LIF, run:

```
network interface modify vserver SVM_name -lif lif_name -service-policy service_policy_name -home-node node_name -home-port port_name {-address IP_address -netmask netmask_value | -subnet-name subnet_name} -firewall -policy policy_name -auto-revert {true|false} -rdma-protocols roce
```

Modifying a LIF to require a particular offload protocol when the LIF is not currently assigned to a port that supports that protocol will produce an error.

## Migrate a LIF

ONTAP also allows you to migrate network interfaces (LIFs) to utilize NFS over RDMA. When performing this migration, you must ensure the destination port is RoCE capable. Beginning with ONTAP 9.12.1, you can complete this procedure in System Manager. When selecting a destination port for the network interface, System Manager will designate whether ports are RoCE capable.

You can only migrate a LIF to an NFS over RDMA configuration if:

- It is an NFS RDMA network interface (LIF) hosted on a RoCE capable port.
- It is an NFS TCP network interface (LIF) hosted on a RoCE capable port.
- It is an NFS TCP network interface (LIF) hosted on a non-RoCE capable port.

For more information about migrating a network interface, refer to [Migrate a LIF](#).

### More Information

- [Create a LIF](#)
- [Create a LIF](#)
- [Modify a LIF](#)
- [Migrate a LIF](#)

## Modify the NFS configuration

In most cases, you will not need to modify the configuration of the NFS-enabled storage VM for NFS over RDMA.

If you are, however, dealing with issues related to Mellanox chips and LIF migration, you should increase the NFSv4 locking grace period. By default, the grace period is set to 45 seconds. Beginning with ONTAP 9.10.1, the grace period has a maximum value of 180 (seconds).

### Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Enter the following command:

```
vserver nfs modify -vserver SVM_name -v4-grace-seconds number_of_seconds
```

For more information about this task, see [Specifying the NFSv4 locking grace period](#).

## Configure SMB with the CLI

### SMB configuration overview with the CLI

You can use ONTAP 9 CLI commands to configure SMB client access to files contained in a new volume or qtree in a new or existing SVM.

SMB (Server Message Block) refers to modern dialects of the Common Internet File System (CIFS) protocol. You will still see CIFS in the ONTAP command-line interface (CLI) and in OnCommand management tools.

Use these procedures if you want to configure SMB access to a volume or qtree in the following way:

- You want to use SMB version 2 or later.
- You want to serve SMB clients only, not NFS clients (not a multiprotocol configuration).
- NTFS file permissions will be used to secure the new volume.
- You have cluster administrator privileges, not SVM administrator privileges.

Cluster administrator privileges are required to create SVMs and LIFs. SVM administrator privileges are sufficient for other SMB configuration tasks.

- You want to use the CLI, not System Manager or an automated scripting tool.

To use System Manager to configure NAS multiprotocol access, see [Provision NAS storage for both Windows and Linux using both NFS and SMB](#).

- You want to use best practices, not explore every available option.

Details about command syntax are available from CLI help and ONTAP man pages.

If you want details about the range of ONTAP SMB protocol capabilities, consult the [SMB reference overview](#).

## Other ways to do this in ONTAP

## SMB configuration workflow

Configuring SMB involves assessing physical storage and networking requirements, and then choosing a workflow that is specific to your goal; configuring SMB access to a new or existing SVM, or adding a volume or qtree to an existing SVM that is already fully configured for SMB access.

## Preparation

### Assess physical storage requirements

Before provisioning SMB storage for clients, you must ensure that there is sufficient space in an existing aggregate for the new volume. If there is not, you can add disks to an existing aggregate or create a new aggregate of the desired type.

### Steps

1. Display available space in existing aggregates: `storage aggregate show`

If there is an aggregate with sufficient space, record its name in the worksheet.

```

cluster::> storage aggregate show
Aggregate Size Available Used% State #Vols Nodes RAID Status
----- ----- ----- ----- ----- ----- ----- ----- -----
aggr_0 239.0GB 11.13GB 95% online 1 node1 raid_dp,
 normal
aggr_1 239.0GB 11.13GB 95% online 1 node1 raid_dp,
 normal
aggr_2 239.0GB 11.13GB 95% online 1 node2 raid_dp,
 normal
aggr_3 239.0GB 11.13GB 95% online 1 node2 raid_dp,
 normal
aggr_4 239.0GB 238.9GB 95% online 5 node3 raid_dp,
 normal
aggr_5 239.0GB 239.0GB 95% online 4 node4 raid_dp,
 normal
 6 entries were displayed.

```

2. If there are no aggregates with sufficient space, add disks to an existing aggregate by using the `storage aggregate add-disks` command, or create a new aggregate by using the `storage aggregate create` command.

## Assess networking requirements

Before providing SMB storage to clients, you must verify that networking is correctly configured to meet the SMB provisioning requirements.

### Before you begin

The following cluster networking objects must be configured:

- Physical and logical ports
- Broadcast domains
- Subnets (if required)
- IPspaces (as required, in addition to the default IPspace)
- Failover groups (as required, in addition to the default failover group for each broadcast domain)
- External firewalls

### Steps

1. Display the available physical and virtual ports: `network port show`
  - When possible, you should use the port with the highest speed for the data network.
  - All components in the data network must have the same MTU setting for best performance.
2. If you are planning to use a subnet name to allocate the IP address and network mask value for a LIF, verify that the subnet exists and has sufficient addresses available: `network subnet show`

Subnets contain a pool of IP addresses that belong to the same layer 3 subnet. Subnets are created by using the `network subnet create` command.

### 3. Display available IPspaces: `network ipspace show`

You can use the default IPspace or a custom IPspace.

### 4. If you want to use IPv6 addresses, verify that IPv6 is enabled on the cluster: `network options ipv6 show`

If required, you can enable IPv6 by using the `network options ipv6 modify` command.

## Decide where to provision new SMB storage capacity

Before you create a new SMB volume or qtree, you must decide whether to place it in a new or existing SVM, and how much configuration the SVM requires. This decision determines your workflow.

### Choices

- If you want to provision a volume or qtree on a new SVM, or on an existing SVM that has SMB enabled but not configured, complete the steps in both “Configuring SMB access to an SVM” and “Adding storage capacity to an SMB-enabled SVM”.

#### [Configuring SMB access to an SVM](#)

#### [Configuring SMB client access to shared storage](#)

You might choose to create a new SVM if one of the following is true:

- You are enabling SMB on a cluster for the first time.
- You have existing SVMs in a cluster in which you do not want to enable SMB support.
- You have one or more SMB-enabled SVMs in a cluster, and you want one of the following connections:
  - To a different Active Directory forest or workgroup.
  - To an SMB server in an isolated namespace (multi-tenancy scenario).You should also choose this option to provision storage on an existing SVM that has SMB enabled but not configured. This might be the case if you created the SVM for SAN access or if no protocols were enabled when the SVM was created.

After enabling SMB on the SVM, proceed to provision a volume or qtree.

- If you want to provision a volume or qtree on an existing SVM that is fully configured for SMB access, complete the steps in “Adding storage capacity to an SMB-enabled SVM”.

#### [Configuring SMB client access to shared storage](#)

## Worksheet for gathering SMB configuration information

The SMB configuration worksheet enables you to collect the required information to set up SMB access for clients.

You should complete one or both sections of the worksheet, depending on the decision you made about where to provision storage:

- If you are configuring SMB access to an SVM, you should complete both sections.

## [Configuring SMB access to an SVM](#)

### [Configuring SMB client access to shared storage](#)

- If you are adding storage capacity to an SMB-enabled SVM, you should complete only the second section.

### [Configuring SMB client access to shared storage](#)

The command man pages contain details about the parameters.

## **Configuring SMB access to an SVM**

### **Parameters for creating an SVM**

You supply these values with the `vserver create` command if you are creating a new SVM.

| Field                                   | Description                                                                                                                                                          | Your value |
|-----------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------|
| <code>-vserver</code>                   | A name you supply for the new SVM that is either a fully qualified domain name (FQDN) or follows another convention that enforces unique SVM names across a cluster. |            |
| <code>-aggregate</code>                 | The name of an aggregate in the cluster with sufficient space for new SMB storage capacity.                                                                          |            |
| <code>-rootvolume</code>                | A unique name you supply for the SVM root volume.                                                                                                                    |            |
| <code>-rootvolume-security-style</code> | Use the NTFS security style for the SVM.                                                                                                                             | ntfs       |
| <code>-language</code>                  | Use the default language setting in this workflow.                                                                                                                   | C.UTF-8    |
| <code>ipspace</code>                    | Optional: IPspaces are distinct IP address spaces in which SVMs reside.                                                                                              |            |

### **Parameters for creating a LIF**

You supply these values with the `network interface create` command when you are creating LIFs.

| Field             | Description                        | Your value |
|-------------------|------------------------------------|------------|
| <code>-lif</code> | A name you supply for the new LIF. |            |

| Field            | Description                                                                                                                                              | Your value |
|------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------|------------|
| -role            | Use the data LIF role in this workflow.                                                                                                                  | data       |
| -data-protocol   | Use only the SMB protocol in this workflow.                                                                                                              | cifs       |
| -home-node       | The node to which the LIF returns when the network interface revert command is run on the LIF.                                                           |            |
| -home-port       | The port or interface group to which the LIF returns when the network interface revert command is run on the LIF.                                        |            |
| -address         | The IPv4 or IPv6 address on the cluster that will be used for data access by the new LIF.                                                                |            |
| -netmask         | The network mask and gateway for the LIF.                                                                                                                |            |
| -subnet          | A pool of IP addresses. Used instead of -address and -netmask to assign addresses and netmasks automatically.                                            |            |
| -firewall-policy | Use the default data firewall policy in this workflow.                                                                                                   | data       |
| -auto-revert     | Optional: Specifies whether a data LIF is automatically reverted to its home node on startup or under other circumstances. The default setting is false. |            |

### Parameters for DNS host name resolution

You supply these values with the vserver services name-service dns create command when you are configuring DNS.

| Field    | Description                  | Your value |
|----------|------------------------------|------------|
| -domains | Up to five DNS domain names. |            |

| Field         | Description                                        | Your value |
|---------------|----------------------------------------------------|------------|
| -name-servers | Up to three IP addresses for each DNS name server. |            |

#### Setting up an SMB server in an Active Directory domain

##### Parameters for time service configuration

You supply these values with the `cluster time-service ntp server create` command when you are configuring time services.

| Field   | Description                                                                    | Your value |
|---------|--------------------------------------------------------------------------------|------------|
| -server | The host name or IP address of the NTP server for the Active Directory domain. |            |

##### Parameters for creating an SMB server in an Active Directory domain

You supply these values with the `vserver cifs create` command when you create a new SMB server and specify domain information.

| Field            | Description                                                                                                                                               | Your value |
|------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------|------------|
| -vserver         | The name of the SVM on which to create the SMB server.                                                                                                    |            |
| -cifs-server     | The name of the SMB server (up to 15 characters).                                                                                                         |            |
| -domain          | The fully qualified domain name (FQDN) of the Active Directory domain to associate with the SMB server.                                                   |            |
| -ou              | Optional: The organizational unit within the Active Directory domain to associate with the SMB server. By default, this parameter is set to CN=Computers. |            |
| -netbios-aliases | Optional: A list of NetBIOS aliases, which are alternate names to the SMB server name.                                                                    |            |
| -comment         | Optional: A text comment for the server. Windows clients can see this SMB server description when browsing servers on the network.                        |            |

## Setting up an SMB server in a workgroup

### Parameters for creating an SMB server in a workgroup

You supply these values with the `vserver cifs create` command when you create a new SMB server and specify supported SMB versions.

| Field                     | Description                                                                                                                        | Your value |
|---------------------------|------------------------------------------------------------------------------------------------------------------------------------|------------|
| <code>-vserver</code>     | The name of the SVM on which to create the SMB server.                                                                             |            |
| <code>-cifs-server</code> | The name of the SMB server (up to 15 characters).                                                                                  |            |
| <code>-workgroup</code>   | The name of the workgroup (up to 15 characters).                                                                                   |            |
| <code>-comment</code>     | Optional: A text comment for the server. Windows clients can see this SMB server description when browsing servers on the network. |            |

### Parameters for creating local users

You supply these values when you create local users by using the `vserver cifs users-and-groups local-user create` command. They are required for SMB servers in workgroups and optional in AD domains.

| Field                     | Description                                                                                                                | Your value |
|---------------------------|----------------------------------------------------------------------------------------------------------------------------|------------|
| <code>-vserver</code>     | The name of the SVM on which to create the local user.                                                                     |            |
| <code>-user-name</code>   | The name of the local user (up to 20 characters).                                                                          |            |
| <code>-full-name</code>   | Optional: The user's full name. If the full name contains a space, enclose the full name within double quotation marks.    |            |
| <code>-description</code> | Optional: A description for the local user. If the description contains a space, enclose the parameter in quotation marks. |            |

| Field                | Description                                                                                                                                         | Your value |
|----------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------|------------|
| -is-account-disabled | Optional: Specifies whether the user account is enabled or disabled. If this parameter is not specified, the default is to enable the user account. |            |

### Parameters for creating local groups

You supply these values when you create local groups by using the `vserver cifs users-and-groups local-group create` command. They are optional for SMB servers in AD domains and workgroups.

| Field        | Description                                                                                                                 | Your value |
|--------------|-----------------------------------------------------------------------------------------------------------------------------|------------|
| -vserver     | The name of the SVM on which to create the local group.                                                                     |            |
| -group-name  | The name of the local group (up to 256 characters).                                                                         |            |
| -description | Optional: A description for the local group. If the description contains a space, enclose the parameter in quotation marks. |            |

### Adding storage capacity to an SMB-enabled SVM

#### Parameters for creating a volume

You supply these values with the `volume create` command if you are creating a volume instead of a qtree.

| Field           | Description                                                                           | Your value |
|-----------------|---------------------------------------------------------------------------------------|------------|
| -vserver        | The name of a new or existing SVM that will host the new volume.                      |            |
| -volume         | A unique descriptive name you supply for the new volume.                              |            |
| -aggregate      | The name of an aggregate in the cluster with sufficient space for the new SMB volume. |            |
| -size           | An integer you supply for the size of the new volume.                                 |            |
| -security-style | Use the NTFS security style for this workflow.                                        | ntfs       |

| Field          | Description                                                    | Your value |
|----------------|----------------------------------------------------------------|------------|
| -junction-path | Location under root (/) where the new volume is to be mounted. |            |

### Parameters for creating a qtree

You supply these values with the `volume qtree create` command if you are creating a qtree instead of a volume.

| Field       | Description                                                                                                                                                      | Your value |
|-------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------|
| -vserver    | The name of the SVM on which the volume containing the qtree resides.                                                                                            |            |
| -volume     | The name of the volume that will contain the new qtree.                                                                                                          |            |
| -qtree      | A unique descriptive name you supply for the new qtree, 64 characters or less.                                                                                   |            |
| -qtree-path | The qtree path argument in the format<br><code>/vol/volume_name/qtree_name</code> can be specified instead of specifying volume and qtree as separate arguments. |            |

### Parameters for creating SMB shares

You supply these values with the `vserver cifs share create` command.

| Field       | Description                                                                                                               | Your value |
|-------------|---------------------------------------------------------------------------------------------------------------------------|------------|
| -vserver    | The name of the SVM on which to create the SMB share.                                                                     |            |
| -share-name | The name of the SMB share that you want to create (up to 256 characters).                                                 |            |
| -path       | The name of the path to the SMB share (up to 256 characters). This path must exist in a volume before creating the share. |            |

| Field             | Description                                                                                                                                      | Your value |
|-------------------|--------------------------------------------------------------------------------------------------------------------------------------------------|------------|
| -share-properties | Optional: A list of share properties. The default settings are oplocks, browsable, changenotify, and show-previous-versions.                     |            |
| -comment          | Optional: A text comment for the server (up to 256 characters). Windows clients can see this SMB share description when browsing on the network. |            |

### Parameters for creating SMB share access control lists (ACLs)

You supply these values with the vserver cifs share access-control create command.

| Field            | Description                                                                                                                                       | Your value                                   |
|------------------|---------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------|
| -vserver         | The name of the SVM on which to create the SMB ACL.                                                                                               |                                              |
| -share           | The name of the SMB share on which to create.                                                                                                     |                                              |
| -user-group-type | The type of the user or group to add to the share's ACL. The default type is windows                                                              | windows                                      |
| -user-or-group   | The user or group to add to the share's ACL. If you specify the user name, you must include the user's domain using the "domain\username" format. |                                              |
| -permission      | Specifies the permissions for the user or group.                                                                                                  | [ No_access   Read   Change   Full_Control ] |

## Configure SMB access to an SVM

### Configure SMB access to an SVM

If you do not already have an SVM configured for SMB client access, you must either create and configure a new SVM or configure an existing SVM. Configuring SMB involves opening SVM root volume access, creating an SMB server, creating a LIF, enabling host-name resolution, configuring name services, and if desired, enabling Kerberos security.

## Create an SVM

If you do not already have at least one SVM in a cluster to provide data access to SMB clients, you must create one.

### Before you begin

- Beginning in ONTAP 9.13.1, you can set a maximum capacity for a storage VM. You can also configure alerts when the SVM approaches a threshold capacity level. For more information, see [Manage SVM capacity](#).

### Steps

- Create an SVM: `vserver create -vserver svm_name -rootvolume root_volume_name -aggregate aggregate_name -rootvolume-security-style ntfs -language C.UTF-8 -ipspace ipspace_name`
  - Use the NTFS setting for the `-rootvolume-security-style` option.
  - Use the default C.UTF-8 `-language` option.
  - The `ipspace` setting is optional.
- Verify the configuration and status of the newly created SVM: `vserver show -vserver vserver_name`

The `Allowed Protocols` field must include CIFS. You can edit this list later.

The `Vserver Operational State` field must display the `running state`. If it displays the `initializing state`, it means that some intermediate operation such as root volume creation failed, and you must delete the SVM and re-create it.

### Examples

The following command creates an SVM for data access in the IPspace `ipspaceA`:

```
cluster1::> vserver create -vserver vs1.example.com -rootvolume root_vs1
-aggregate aggr1
-rootvolume-security-style ntfs -language C.UTF-8 -ipspace ipspaceA

[Job 2059] Job succeeded:
Vserver creation completed
```

The following command shows that an SVM was created with a root volume of 1 GB, and it was started automatically and is in `running state`. The root volume has a default export policy that does not include any rules, so the root volume is not exported upon creation.

```
cluster1::> vserver show -vserver vs1.example.com
 Vserver: vs1.example.com
 Vserver Type: data
 Vserver Subtype: default
 Vserver UUID: b8375669-19b0-11e5-b9d1-
00a0983d9736
 Root Volume: root_vs1
 Aggregate: aggr1
 NIS Domain: -
 Root Volume Security Style: ntfs
 LDAP Client: -
 Default Volume Language Code: C.UTF-8
 Snapshot Policy: default
 Comment:
 Quota Policy: default
 List of Aggregates Assigned: -
 Limit on Maximum Number of Volumes allowed: unlimited
 Vserver Admin State: running
 Vserver Operational State: running
 Vserver Operational State Stopped Reason: -
 Allowed Protocols: nfs, cifs, fcp, iscsi, ndmp
 Disallowed Protocols: -
 QoS Policy Group: -
 Config Lock: false
 IPspace Name: ipspaceA
```

 Beginning in ONTAP 9.13.1, you can set an adaptive QoS policy group template, applying a throughput floor and ceiling limit to volumes in the SVM. You can only apply this policy after you create the SVM. To learn more about this process, see [Set an adaptive policy group template](#).

## Verify that the SMB protocol is enabled on the SVM

Before you can configure and use SMB on SVMs, you must verify that the protocol is enabled.

### About this task

This is typically done during SVM setup, but if you did not enable the protocol during setup, you can enable it later by using the `vserver add-protocols` command.

You cannot add or remove a protocol from a LIF once it is created.

You can also disable protocols on SVMs using the `vserver remove-protocols` command.

### Steps

1. Check which protocols are currently enabled and disabled for the SVM: `vserver show -vserver vserver_name -protocols`

You can also use the `vserver show-protocols` command to view the currently enabled protocols on all SVMs in the cluster.

2. If necessary, enable or disable a protocol:

- To enable the SMB protocol: `vserver add-protocols -vserver vserver_name -protocols cifs`
- To disable a protocol: `vserver remove-protocols -vserver vserver_name -protocols protocol_name[,protocol_name,...]`

3. Confirm that the enabled and disabled protocols were updated correctly: `vserver show -vserver vserver_name -protocols`

#### Example

The following command displays which protocols are currently enabled and disabled (allowed and disallowed) on the SVM named vs1:

```
vs1::> vserver show -vserver vs1.example.com -protocols
Vserver Allowed Protocols Disallowed Protocols

vs1.example.com cifs nfs, fcp, iscsi, ndmp
```

The following command allows access over SMB by adding `cifs` to the list of enabled protocols on the SVM named vs1:

```
vs1::> vserver add-protocols -vserver vs1.example.com -protocols cifs
```

#### Open the export policy of the SVM root volume

The default export policy of the SVM root volume must include a rule to allow all clients open access through SMB. Without such a rule, all SMB clients are denied access to the SVM and its volumes.

#### About this task

When a new SVM is created, a default export policy (called `default`) is created automatically for the root volume of the SVM. You must create one or more rules for the default export policy before clients can access data on the SVM.

You should verify that all SMB access is open in the default export policy, and later restrict access to individual volumes by creating custom export policies for individual volumes or qtrees.

#### Steps

1. If you are using an existing SVM, check the default root volume export policy: `vserver export-policy rule show`

The command output should be similar to the following:

```

cluster::> vserver export-policy rule show -vserver vs1.example.com
-policynname default -instance

 Vserver: vs1.example.com
 Policy Name: default
 Rule Index: 1
 Access Protocol: cifs
Client Match Hostname, IP Address, Netgroup, or Domain: 0.0.0.0/0
 RO Access Rule: any
 RW Access Rule: any
User ID To Which Anonymous Users Are Mapped: 65534
 Superuser Security Types: any
 Honor SetUID Bits in SETATTR: true
 Allow Creation of Devices: true

```

If such a rule exists that allows open access, this task is complete. If not, proceed to the next step.

2. Create an export rule for the SVM root volume: `vserver export-policy rule create -vserver vserver_name -policynname default -ruleindex 1 -protocol cifs -clientmatch 0.0.0.0/0 -rorule any -rwrule any -superuser any`
3. Verify rule creation by using the `vserver export-policy rule show` command.

## Results

Any SMB client can now access any volume or qtree created on the SVM.

## Create a LIF

A LIF is an IP address associated with a physical or logical port. If there is a component failure, a LIF can fail over to or be migrated to a different physical port, thereby continuing to communicate with the network.

### Before you begin

- The underlying physical or logical network port must have been configured to the administrative `up` status.
- If you are planning to use a subnet name to allocate the IP address and network mask value for a LIF, the subnet must already exist.

Subnets contain a pool of IP addresses that belong to the same layer 3 subnet. They are created using the `network subnet create` command.

- The mechanism for specifying the type of traffic handled by a LIF has changed. For ONTAP 9.5 and earlier, LIFs used roles to specify the type of traffic it would handle. Beginning with ONTAP 9.6, LIFs use service policies to specify the type of traffic it would handle.

### About this task

- You can create both IPv4 and IPv6 LIFs on the same network port.
- If you have a large number of LIFs in your cluster, you can verify the LIF capacity supported on the cluster by using the `network interface capacity show` command and the LIF capacity supported on each

node by using the network interface capacity details show command (at the advanced privilege level).

- Beginning with ONTAP 9.7, if other LIFs already exist for the SVM in the same subnet, you do not need to specify the home port of the LIF. ONTAP automatically chooses a random port on the specified home node in the same broadcast domain as the other LIFs already configured in the same subnet.

## Steps

- Create a LIF:

```
network interface create -vserver vserver_name -lif lif_name -role data -data-protocol cifs -home-node node_name -home-port port_name {-address IP_address -netmask IP_address | -subnet-name subnet_name} -firewall-policy data -auto -revert {true|false}
```

### ONTAP 9.5 and earlier

```
network interface create -vserver vserver_name -lif lif_name -role data -data-protocol cifs -home-node node_name -home-port port_name {-address IP_address -netmask IP_address | -subnet-name subnet_name} -firewall-policy data -auto -revert {true|false}
```

### ONTAP 9.6 and later

```
network interface create -vserver vserver_name -lif lif_name -service-policy service_policy_name -home-node node_name -home-port port_name {-address IP_address -netmask IP_address | -subnet-name subnet_name} -firewall-policy data -auto-revert {true|false}
```

- The `-role` parameter is not required when creating a LIF using a service policy (beginning with ONTAP 9.6).
- The `-data-protocol` parameter must be specified when the LIF is created, and cannot be modified later without destroying and re-creating the data LIF.

The `-data-protocol` parameter is not required when creating a LIF using a service policy (beginning with ONTAP 9.6).

- `-home-node` is the node to which the LIF returns when the `network interface revert` command is run on the LIF.

You can also specify whether the LIF should automatically revert to the `home-node` and `home-port` with the `-auto-revert` option.

- `-home-port` is the physical or logical port to which the LIF returns when the `network interface revert` command is run on the LIF.
- You can specify an IP address with the `-address` and `-netmask` options, or you enable allocation from a subnet with the `-subnet_name` option.
- When using a subnet to supply the IP address and network mask, if the subnet was defined with a gateway, a default route to that gateway is added automatically to the SVM when a LIF is created using that subnet.

- If you assign IP addresses manually (without using a subnet), you might need to configure a default route to a gateway if there are clients or domain controllers on a different IP subnet. The `network route create` man page contains information about creating a static route within an SVM.
- For the `-firewall-policy` option, use the same default data as the LIF role.

You can create and add a custom firewall policy later if desired.

Beginning with ONTAP 9.10.1, firewall policies are deprecated and wholly replaced with LIF service policies. For more information, see [Configure firewall policies for LIFs](#).

- `-auto-revert` allows you to specify whether a data LIF is automatically reverted to its home node under circumstances such as startup, changes to the status of the management database, or when the network connection is made. The default setting is `false`, but you can set it to `false` depending on network management policies in your environment.

## 2. Verify that the LIF was created successfully:

```
network interface show
```

## 3. Verify that the configured IP address is reachable:

| To verify an... | Use...                     |
|-----------------|----------------------------|
| IPv4 address    | <code>network ping</code>  |
| IPv6 address    | <code>network ping6</code> |

## Examples

The following command creates a LIF and specifies the IP address and network mask values using the `-address` and `-netmask` parameters:

```
network interface create -vserver vs1.example.com -lif datalif1 -role data
-data-protocol cifs -home-node node-4 -home-port e1c -address 192.0.2.145
-netmask 255.255.255.0 -firewall-policy data -auto-revert true
```

The following command creates a LIF and assigns IP address and network mask values from the specified subnet (named `client1_sub`):

```
network interface create -vserver vs3.example.com -lif datalif3 -role data
-data-protocol cifs -home-node node-3 -home-port e1c -subnet-name
client1_sub -firewall-policy data -auto-revert true
```

The following command shows all the LIFs in cluster-1. Data LIFs `datalif1` and `datalif3` are configured with IPv4 addresses, and `datalif4` is configured with an IPv6 address:

```
network interface show
```

| Vserver                   | Logical Interface | Status Admin/Oper | Network Address/Mask | Current Node | Current Is Port |
|---------------------------|-------------------|-------------------|----------------------|--------------|-----------------|
| Home                      |                   |                   |                      |              |                 |
| cluster-1                 | cluster_mgmt      | up/up             | 192.0.2.3/24         | node-1       | e1a             |
| true                      |                   |                   |                      |              |                 |
| node-1                    | clus1             | up/up             | 192.0.2.12/24        | node-1       | e0a             |
| true                      |                   |                   |                      |              |                 |
| true                      | clus2             | up/up             | 192.0.2.13/24        | node-1       | e0b             |
| true                      |                   |                   |                      |              |                 |
| node-2                    | mgmt1             | up/up             | 192.0.2.68/24        | node-1       | e1a             |
| true                      |                   |                   |                      |              |                 |
| true                      | clus1             | up/up             | 192.0.2.14/24        | node-2       | e0a             |
| true                      |                   |                   |                      |              |                 |
| true                      | clus2             | up/up             | 192.0.2.15/24        | node-2       | e0b             |
| true                      |                   |                   |                      |              |                 |
| true                      | mgmt1             | up/up             | 192.0.2.69/24        | node-2       | e1a             |
| vs1.example.com           | datalif1          | up/down           | 192.0.2.145/30       | node-1       | e1c             |
| true                      |                   |                   |                      |              |                 |
| vs3.example.com           | datalif3          | up/up             | 192.0.2.146/30       | node-2       | e0c             |
| true                      |                   |                   |                      |              |                 |
| true                      | datalif4          | up/up             | 2001::2/64           | node-2       | e0c             |
| 5 entries were displayed. |                   |                   |                      |              |                 |

The following command shows how to create a NAS data LIF that is assigned with the default-data-files service policy:

```
network interface create -vserver vs1 -lif lif2 -home-node node2 -homeport e0d -service-policy default-data-files -subnet-name ipspace1
```

### Enable DNS for host-name resolution

You can use the vserver services name-service dns command to enable DNS on an SVM, and configure it to use DNS for host-name resolution. Host names are

resolved using external DNS servers.

## Before you begin

A site-wide DNS server must be available for host name lookups.

You should configure more than one DNS server to avoid a single-point-of-failure. The `vserver services name-service dns create` command issues a warning if you enter only one DNS server name.

## About this task

The *Network Management Guide* contains information about configuring dynamic DNS on the SVM.

## Steps

1. Enable DNS on the SVM: `vserver services name-service dns create -vserver vserver_name -domains domain_name -name-servers ip_addresses -state enabled`

The following command enables external DNS server servers on the SVM vs1:

```
vserver services name-service dns create -vserver vs1.example.com
-domains example.com -name-servers 192.0.2.201,192.0.2.202 -state
enabled
```

Beginning with ONTAP 9.2, the `vserver services name-service dns create` command performs an automatic configuration validation and reports an error message if ONTAP cannot contact the name server.

2. Display the DNS domain configurations by using the `vserver services name-service dns show` command.

The following command displays the DNS configurations for all SVMs in the cluster:

```
vserver services name-service dns show
```

| Vserver         | State   | Domains     | Name | Servers                     |
|-----------------|---------|-------------|------|-----------------------------|
| cluster1        | enabled | example.com |      | 192.0.2.201,<br>192.0.2.202 |
| vs1.example.com | enabled | example.com |      | 192.0.2.201,<br>192.0.2.202 |

The following command displays detailed DNS configuration information for SVM vs1:

```
vserver services name-service dns show -vserver vs1.example.com
 Vserver: vs1.example.com
 Domains: example.com
 Name Servers: 192.0.2.201, 192.0.2.202
 Enable/Disable DNS: enabled
 Timeout (secs): 2
 Maximum Attempts: 1
```

3. Validate the status of the name servers by using the `vserver services name-service dns check` command.

The `vserver services name-service dns check` command is available beginning with ONTAP 9.2.

```
vserver services name-service dns check -vserver vs1.example.com

Vserver Name Server Status Status Details
----- ----- -----
----- -----
vs1.example.com 10.0.0.50 up Response time (msec): 2
vs1.example.com 10.0.0.51 up Response time (msec): 2
```

## Set up an SMB server in an Active Directory domain

### Configure time services

Before creating an SMB server in an Active Domain controller, you must ensure that the cluster time and the time on the domain controllers of the domain to which the SMB server will belong matches to within five minutes.

### About this task

You should configure cluster NTP services to use the same NTP servers for time synchronization that the Active Directory domain uses.

Beginning with ONTAP 9.5, you can set up your NTP server with symmetric authentication.

### Steps

1. Configure time services by using the `cluster time-service ntp server create` command.
  - To configure time services without symmetric authentication enter the following command: `cluster time-service ntp server create -server server_ip_address`
  - To configure time services with symmetric authentication, enter the following command: `cluster time-service ntp server create -server server_ip_address -key-id key_id`  
`cluster time-service ntp server create -server 10.10.10.1`  
`cluster time-service ntp server create -server 10.10.10.2`
2. Verify that time services are set up correctly by using the `cluster time-service ntp server show`

command.

```
cluster time-service ntp server show
```

| Server     | Version |
|------------|---------|
| 10.10.10.1 | auto    |
| 10.10.10.2 | auto    |

#### Commands for managing symmetric authentication on NTP servers

Beginning with ONTAP 9.5, Network Time Protocol (NTP) version 3 is supported. NTPv3 includes symmetric authentication using SHA-1 keys which increases network security.

| To do this...                                                                                                                                                | Use this command...                                                                                                                                                                                                                                                                                                                 |
|--------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Configure an NTP server without symmetric authentication                                                                                                     | <code>cluster time-service ntp server create -server server_name</code>                                                                                                                                                                                                                                                             |
| Configure an NTP server with symmetric authentication                                                                                                        | <code>cluster time-service ntp server create -server server_ip_address -key-id key_id</code>                                                                                                                                                                                                                                        |
| Enable symmetric authentication for an existing NTP server<br>An existing NTP server can be modified to enable authentication by adding the required key-id. | <code>cluster time-service ntp server modify -server server_name -key-id key_id</code>                                                                                                                                                                                                                                              |
| Configure a shared NTP key                                                                                                                                   | <code>cluster time-service ntp key create -id shared_key_id -type shared_key_type -value shared_key_value</code><br><br> Shared keys are referred to by an ID. The ID, its type, and value must be identical on both the node and the NTP server |
| Configure an NTP server with an unknown key ID                                                                                                               | <code>cluster time-service ntp server create -server server_name -key-id key_id</code>                                                                                                                                                                                                                                              |
| Configure a server with a key ID not configured on the NTP server.                                                                                           | <code>cluster time-service ntp server create -server server_name -key-id key_id</code><br><br> The key ID, type, and value must be identical to the key ID, type, and value configured on the NTP server.                                        |

| To do this...                    | Use this command...                                                                              |
|----------------------------------|--------------------------------------------------------------------------------------------------|
| Disable symmetric authentication | <code>cluster time-service ntp server modify -server server_name -authentication disabled</code> |

#### Create an SMB server in an Active Directory domain

You can use the `vserver cifs create` command to create an SMB server on the SVM and specify the Active Directory (AD) domain to which it belongs.

#### Before you begin

The SVM and LIFs that you are using to serve data must have been configured to allow the SMB protocol. The LIFs must be able to connect to the DNS servers that are configured on the SVM and to an AD domain controller of the domain to which you want to join the SMB server.

Any user who is authorized to create machine accounts in the AD domain to which you are joining the SMB server can create the SMB server on the SVM. This can include users from other domains.

Beginning with ONTAP 9.7, your AD administrator can provide you with a URI to a keytab file as an alternative to providing you with a name and password to a privileged Windows account. When you receive the URI, include it in the `-keytab-uri` parameter with the `vserver cifs` commands.

#### About this task

When creating an SMB server in an Activity Directory domain:

- You must use the fully qualified domain name (FQDN) when specifying the domain.
- The default setting is to add the SMB server machine account to the Active Directory CN=Computer object.
- You can choose to add the SMB server to a different organizational unit (OU) by using the `-ou` option.
- You can optionally choose to add a comma-delimited list of one or more NetBIOS aliases (up to 200) for the SMB server.

Configuring NetBIOS aliases for an SMB server can be useful when you are consolidating data from other file servers to the SMB server and want the SMB server to respond to the original servers' names.

The `vserver cifs` man pages contain additional optional parameters and naming requirements.

Beginning with ONTAP 9.1, you can enable SMB version 2.0 to connect to a domain controller (DC). Doing so is necessary if you have disabled SMB 1.0 on domain controllers. Beginning with ONTAP 9.2, SMB 2.0 is enabled by default.

Beginning with ONTAP 9.8, you can specify that connections to domain controllers be encrypted. ONTAP requires encryption for domain controller communications when the `-encryption-required-for-dc-connection` option is set to `true`; the default is `false`. When the option is set, only the SMB3 protocol will be used for ONTAP-DC connections, because encryption is only supported by SMB3. .

[SMB management](#) contains more information about SMB server configuration options.

#### Steps

1. Verify that SMB is licensed on your cluster: `system license show -package cifs`

If it is not, contact your sales representative.

A CIFS license is not required if the SMB server will be used for authentication only.

2. Create the SMB server in an AD domain: `vserver cifs create -vserver vserver_name -cifs-server smb_server_name -domain FQDN [-ou organizational_unit][-netbios-aliases NetBIOS_name, ...] [-keytab-uri {(ftp|http)://hostname|IP_address}] [-comment text]`

When joining a domain, this command might take several minutes to finish.

The following command creates the SMB server “`smb_server01`” in the domain “`example.com`”:

```
cluster1::> vserver cifs create -vserver vs1.example.com -cifs-server
smb_server01 -domain example.com
```

The following command creates the SMB server “`smb_server02`” in the domain “`mydomain.com`” and authenticates the ONTAP administrator with a keytab file:

```
cluster1::> vserver cifs create -vserver vs1.mydomain.com -cifs-server
smb_server02 -domain mydomain.com -keytab-uri
http://admin.mydomain.com/ontap1.keytab
```

3. Verify the SMB server configuration by using the `vserver cifs show` command.

In this example, the command output shows that an SMB server named “`SMB_SERVER01`” was created on SVM `vs1.example.com`, and was joined to the “`example.com`” domain.

```
cluster1::> vserver cifs show -vserver vs1

Vserver: vs1.example.com
CIFS Server NetBIOS Name: SMB_SERVER01
NetBIOS Domain/Workgroup Name: EXAMPLE
Fully Qualified Domain Name: EXAMPLE.COM
Default Site Used by LIFs Without Site Membership:
Authentication Style: domain
CIFS Server Administrative Status: up
CIFS Server Description: -
List of NetBIOS Aliases: -
```

4. If desired, enable encrypted communication with the domain controller (ONTAP 9.8 and later): `vserver cifs security modify -vserver svm_name -encryption-required-for-dc-connection true`

## Examples

The following command creates a SMB server named “smb\_server02” on SVM vs2.example.com in the “example.com” domain. The machine account is created in the “OU=eng,OU=corp,DC=example,DC=com” container. The SMB server is assigned a NetBIOS alias.

```
cluster1::> vserver cifs create -vserver vs2.example.com -cifs-server
smb_server02 -domain example.com -ou OU=eng,OU=corp -netbios-aliases
old_cifs_server01

cluster1::> vserver cifs show -vserver vs1
 Vserver: vs2.example.com
 CIFS Server NetBIOS Name: SMB_SERVER02
 NetBIOS Domain/Workgroup Name: EXAMPLE
 Fully Qualified Domain Name: EXAMPLE.COM
Default Site Used by LIFs Without Site Membership:
 Authentication Style: domain
 CIFS Server Administrative Status: up
 CIFS Server Description: -
 List of NetBIOS Aliases: OLD_CIFS_SERVER01
```

The following command enables a user from a different domain, in this case an administrator of a trusted domain, to create a SMB server named “smb\_server03” on SVM vs3.example.com. The –domain option specifies the name of the home domain (specified in the DNS configuration) in which you want to create the SMB server. The username option specifies the administrator of the trusted domain.

- Home domain: example.com
  - Trusted domain: trust.lab.com
  - Username for the trusted domain: Administrator1

```
cluster1::> vserver cifs create -vserver vs3.example.com -cifs-server
smb server03 -domain example.com
```

Username: Administrator1@trust.lab.com  
Password: . . .

## Create keytab files for SMB authentication

Beginning with ONTAP 9.7, ONTAP supports SVM authentication with Active Directory (AD) servers using keytab files. AD administrators generate a keytab file and make it available to ONTAP administrators as a uniform resource identifier (URI), which is supplied when `vserver cifs` commands require Kerberos authentication with the AD domain.

AD administrators can create the keytab files using the standard Windows Server `ktpass` command. The command should be run on the primary domain where authentication is required. The `ktpass` command can be used to generate keytab files only for primary domain users; keys generated using trusted-domain users are not supported.

Keytab files are generated for specific ONTAP admin users. As long as the admin user's password does not change, the keys generated for the specific encryption type and domain will not change. Therefore, a new keytab file is required whenever the admin user's password is changed.

The following encryption types are supported:

- AES256-SHA1
- DES-CBC-MD5

ONTAP does not support DES-CBC-CRC encryption type.

- RC4-HMAC

AES256 is the highest encryption type and should be used if enabled on the ONTAP system.

Keytab files can be generated by specifying either the admin password or by using a randomly-generated password. However, at any given time only one password option can be used, because a private key specific to the admin user is needed at the AD server for decrypting the keys inside the keytab file. Any change in the private key for a specific admin will invalidate the keytab file.

## **Set up an SMB server in a workgroup**

### **Set up an SMB server in a workgroup overview**

Setting up an SMB server as a member in a workgroup consists of creating the SMB server, and then creating local users and groups.

You can configure an SMB server in a workgroup when the Microsoft Active Directory domain infrastructure is not available.

An SMB server in workgroup mode supports only NTLM authentication and does not support Kerberos authentication.

### **Create an SMB server in a workgroup**

You can use the `vserver cifs create` command to create an SMB server on the SVM and specify the workgroup to which it belongs.

#### **Before you begin**

The SVM and LIFs that you are using to serve data must have been configured to allow the SMB protocol. The LIFs must be able to connect to the DNS servers that are configured on the SVM.

#### **About this task**

SMB servers in workgroup mode do not support the following SMB features:

- SMB3 Witness protocol
- SMB3 CA shares
- SQL over SMB
- Folder Redirection
- Roaming Profiles

- Group Policy Object (GPO)
- Volume Snapshot Service (VSS)

The `vserver cifs` man pages contain additional optional configuration parameters and naming requirements.

## Steps

1. Verify that SMB is licensed on your cluster: `system license show -package cifs`

If it is not, contact your sales representative.

A CIFS license is not required if the SMB server will be used for authentication only.

2. Create the SMB server in a workgroup: `vserver cifs create -vserver vserver_name -cifs -server cifs_server_name -workgroup workgroup_name [-comment text]`

The following command creates the SMB server “`smb_server01`” in the workgroup “`workgroup01`”:

```
cluster1::> vserver cifs create -vserver vs1.example.com -cifs-server
SMB_SERVER01 -workgroup workgroup01
```

3. Verify the SMB server configuration by using the `vserver cifs show` command.

In the following example, the command output shows that a SMB server named “`smb_server01`” was created on SVM `vs1.example.com` in the workgroup “`workgroup01`”:

```
cluster1::> vserver cifs show -vserver vs0

Vserver: vs1.example.com
CIFS Server NetBIOS Name: SMB_SERVER01
NetBIOS Domain/Workgroup Name: workgroup01
Fully Qualified Domain Name: -
Organizational Unit: -
Default Site Used by LIFs Without Site Membership: -
Workgroup Name: workgroup01
Authentication Style: workgroup
CIFS Server Administrative Status: up
CIFS Server Description:
List of NetBIOS Aliases: -
```

## After you finish

For a CIFS server in a workgroup, you must create local users, and optionally local groups, on the SVM.

## Related information

[SMB management](#)

## Create local user accounts

You can create a local user account that can be used to authorize access to data contained in the SVM over an SMB connection. You can also use local user accounts for authentication when creating an SMB session.

### About this task

Local user functionality is enabled by default when the SVM is created.

When you create a local user account, you must specify a user name and you must specify the SVM with which to associate the account.

The `vserver cifs users-and-groups local-user` man pages contain details about optional parameters and naming requirements.

### Steps

1. Create the local user: `vserver cifs users-and-groups local-user create -vserver vserver_name -user-name user_name optional_parameters`

The following optional parameters might be useful:

- `-full-name`

The user's full name.

- `-description`

A description for the local user.

- `-is-account-disabled {true|false}`

Specifies whether the user account is enabled or disabled. If this parameter is not specified, the default is to enable the user account.

The command prompts for the local user's password.

2. Enter a password for the local user, and then confirm the password.
3. Verify that the user was successfully created: `vserver cifs users-and-groups local-user show -vserver vserver_name`

### Example

The following example creates a local user “SMB\_SERVER01\sue”, with a full name “Sue Chang”, associated with SVM vs1.example.com:

```
cluster1::> vserver cifs users-and-groups local-user create -vserver
vs1.example.com -user-name SMB_SERVER01\sue -full-name "Sue Chang"
```

Enter the password:

Confirm the password:

```
cluster1::> vserver cifs users-and-groups local-user show
Vserver User Name Full Name Description

vs1 SMB_SERVER01\Administrator Built-in administrator
account
vs1 SMB_SERVER01\sue Sue Chang
```

### Create local groups

You can create local groups that can be used for authorizing access to data associated with the SVM over an SMB connection. You can also assign privileges that define what user rights or capabilities a member of the group has.

#### About this task

Local group functionality is enabled by default when the SVM is created.

When you create a local group, you must specify a name for the group and you must specify the SVM with which to associate the group. You can specify a group name with or without the local domain name, and you can optionally specify a description for the local group. You cannot add a local group to another local group.

The `vserver cifs users-and-groups local-group` man pages contain details about optional parameters and naming requirements.

#### Steps

1. Create the local group: `vserver cifs users-and-groups local-group create -vserver vserver_name -group-name group_name`

The following optional parameter might be useful:

- `-description`

A description for the local group.

2. Verify that the group was successfully created: `vserver cifs users-and-groups local-group show -vserver vserver_name`

#### Example

The following example creates a local group “SMB\_SERVER01\engineering” associated with SVM vs1:

```

cluster1::> vserver cifs users-and-groups local-group create -vserver
vs1.example.com -group-name SMB_SERVER01\engineering

cluster1::> vserver cifs users-and-groups local-group show -vserver
vs1.example.com
Vserver Group Name Description

vs1.example.com BUILTIN\Administrators Built-in Administrators
group
vs1.example.com BUILTIN\Backup Operators Backup Operators group
vs1.example.com BUILTIN\Power Users Restricted administrative
privileges
vs1.example.com BUILTIN\Users All users
vs1.example.com SMB_SERVER01\engineering
vs1.example.com SMB_SERVER01\sales

```

## After you finish

You must add members to the new group.

### Manage local group membership

You can manage local group membership by adding and removing local or domain users, or adding and removing domain groups. This is useful if you want to control access to data based on access controls placed on the group, or if you want users to have privileges associated with that group.

### About this task

If you no longer want a local user, domain user, or domain group to have access rights or privileges based on membership in a group, you can remove the member from the group.

You must keep the following in mind when adding members to a local group:

- You cannot add users to the special *Everyone* group.
- You cannot add a local group to another local group.
- To add a domain user or group to a local group, ONTAP must be able to resolve the name to a SID.

You must keep the following in mind when removing members from a local group:

- You cannot remove members from the special *Everyone* group.
- To remove a member from a local group, ONTAP must be able to resolve their name to a SID.

### Steps

1. Add a member to or remove a member from a group.

- Add a member: `vserver cifs users-and-groups local-group add-members -vserver vserver_name -group-name group_name -member-names name[,...]`

You can specify a comma-delimited list of local users, domain users, or domain groups to add to the

specified local group.

- Remove a member: `vserver cifs users-and-groups local-group remove-members -vserver vserver_name -group-name group_name -member-names name[,...]`

You can specify a comma-delimited list of local users, domain users, or domain groups to remove from the specified local group.

## Examples

The following example adds a local user “SMB\_SERVER01\sue” to the local group “SMB\_SERVER01\engineering” on SVM vs1.example.com:

```
cluster1::> vserver cifs users-and-groups local-group add-members -vserver
vs1.example.com -group-name SMB_SERVER01\engineering -member-names
SMB_SERVER01\sue
```

The following example removes the local users “SMB\_SERVER01\sue” and “SMB\_SERVER01\james” from the local group “SMB\_SERVER01\engineering” on SVM vs1.example.com:

```
cluster1::> vserver cifs users-and-groups local-group remove-members
-vserver vs1.example.com -group-name SMB_SERVER\engineering -member-names
SMB_SERVER\sue,SMB_SERVER\james
```

## Verify enabled SMB versions

Your ONTAP 9 release determines which SMB versions are enabled by default for connections with clients and domain controllers. You should verify that the SMB server supports the clients and functionality required in your environment.

### About this task

For connections with both clients and domain controllers, you should enable SMB 2.0 and later whenever possible. For security reasons, you should avoid using SMB 1.0, and you should disable it if you have verified that it is not required in your environment.

In ONTAP 9, SMB versions 2.0 and later are enabled by default for client connections, but the version of SMB 1.0 enabled by default depends on your ONTAP release.

- Beginning with ONTAP 9.1 P8, SMB 1.0 can be disabled on SVMs.

The `-smb1-enabled` option to the `vserver cifs options modify` command enables or disables SMB 1.0.

- Beginning with ONTAP 9.3, it is disabled by default on new SVMs.

If your SMB server is in an Active Directory (AD) domain, you can enable SMB 2.0 to connect to a domain controller (DC) beginning with ONTAP 9.1. Doing so is necessary if you have disabled SMB 1.0 on DCs. Beginning with ONTAP 9.2, SMB 2.0 is enabled by default for DC connections.

If `-smb1-enabled-for-dc-connections` is set to `false` while `-smb1-enabled` is set to `true`, ONTAP denies SMB 1.0 connections as the client, but continues to accept inbound SMB 1.0 connections as the server.

[SMB management](#) contains details about supported SMB versions and functionality.

## Steps

1. Set the privilege level to advanced: `set -privilege advanced`
2. Verify which SMB versions are enabled: `vserver cifs options show`

You can scroll down the list to view the SMB versions enabled for client connections, and if you are configuring an SMB server in an AD domain, for AD domain connections.

3. Enable or disable the SMB protocol for client connections as required:

- To enable an SMB version: `vserver cifs options modify -vserver vserver_name smb_version true`
- To disable an SMB version: `vserver cifs options modify -vserver vserver_name smb_version false`

Possible values for `smb_version`:

- `-smb1-enabled`
- `-smb2-enabled`
- `-smb3-enabled`
- `-smb31-enabled`

The following command enables SMB 3.1 on SVM vs1.example.com:

```
cluster1::>*> vserver cifs options modify -vserver vs1.example.com -smb31-enabled true
```

4. If your SMB server is in an Active Directory domain, enable or disable the SMB protocol for DC connections as required:

- To enable an SMB version: `vserver cifs security modify -vserver vserver_name -smb2-enabled-for-dc-connections true`
- To disable an SMB version: `vserver cifs security modify -vserver vserver_name -smb2-enabled-for-dc-connections false`

5. Return to the admin privilege level: `set -privilege admin`

## Map the SMB server on the DNS server

Your site's DNS server must have an entry pointing the SMB server name, and any NetBIOS aliases, to the IP address of the data LIF so that Windows users can map a drive to the SMB server name.

### Before you begin

You must have administrative access to your site's DNS server. If you do not have administrative access, you

must ask the DNS administrator to perform this task.

### About this task

If you use NetBIOS aliases for the SMB server name, it is a best practice to create DNS server entry points for each alias.

### Steps

1. Log in to the DNS server.
2. Create forward (A - Address record) and reverse (PTR - Pointer record) lookup entries to map the SMB server name to the IP address of the data LIF.
3. If you use NetBIOS aliases, create an Alias canonical name (CNAME resource record) lookup entry to map each alias to the IP address of the SMB server's data LIF.

### Results

After the mapping is propagated across the network, Windows users can map a drive to the SMB server name or its NetBIOS aliases.

## Configure SMB client access to shared storage

### Configure SMB client access to shared storage

To provide SMB client access to shared storage on an SVM, you must create a volume or qtree to provide a storage container, and then create or modify a share for that container. You can then configure share and file permissions, and test access from client systems.

#### Before you begin

- SMB must be completely set up on the SVM.
- Any updates to your name services configuration must be complete.
- Any additions or modifications to an Active Directory domain or workgroup configuration must be complete.

### Create a volume or qtree storage container

#### Create a volume

\*

You can create a volume and specify its junction point and other properties by using the `volume create` command.

### About this task

A volume must include a *junction path* for its data to be made available to clients. You can specify the junction path when you create a new volume. If you create a volume without specifying a junction path, you must *mount* the volume in the SVM namespace using the `volume mount` command.

#### Before you begin

- SMB should be set up and running.
- The SVM security style must be NTFS.
- Beginning in ONTAP 9.13.1, you can create volumes with capacity analytics and Activity Tracking enabled. To enable capacity or Activity Tracking, issue the `volume create` command with `-analytics-state` or

`-activity-tracking-state` set to on.

To learn more about capacity analytics and Activity Tracking, see [Enable File System Analytics](#).

## Steps

1. Create the volume with a junction point: `volume create -vserver svm_name -volume volume_name -aggregate aggregate_name -size {integer[KB|MB|GB|TB|PB]} -security-style ntfs -junction-path junction_path`

The choices for `-junction-path` are the following:

- Directly under root, for example, `/new_vol`

You can create a new volume and specify that it be mounted directly to the SVM root volume.

- Under an existing directory, for example, `/existing_dir/new_vol`

You can create a new volume and specify that it be mounted to an existing volume (in an existing hierarchy), expressed as a directory.

If you want to create a volume in a new directory (in a new hierarchy under a new volume), for example, `/new_dir/new_vol`, then you must first create a new parent volume that is junctioned to the SVM root volume. You would then create the new child volume in the junction path of the new parent volume (new directory).

2. Verify that the volume was created with the desired junction point: `volume show -vserver svm_name -volume volume_name -junction`

## Examples

The following command creates a new volume named `users1` on the SVM `vs1.example.com` and the aggregate `aggr1`. The new volume is made available at `/users`. The volume is 750 GB in size, and its volume guarantee is of type `volume` (by default).

```
cluster1::> volume create -vserver vs1.example.com -volume users
-aggregate aggr1 -size 750g -junction-path /users
[Job 1642] Job succeeded: Successful

cluster1::> volume show -vserver vs1.example.com -volume users -junction
Junction Junction
Vserver Volume Active Junction Path Path Source

vs1.example.com users1 true /users RW_volume
```

The following command creates a new volume named “`home4`” on the SVM “`vs1.example.com`” and the aggregate “`aggr1`”. The directory `/eng/` already exists in the namespace for the `vs1` SVM, and the new volume is made available at `/eng/home`, which becomes the home directory for the `/eng/` namespace. The volume is 750 GB in size, and its volume guarantee is of type `volume` (by default).

```

cluster1::> volume create -vserver vs1.example.com -volume home4
-aggregate aggr1 -size 750g -junction-path /eng/home
[Job 1642] Job succeeded: Successful

cluster1::> volume show -vserver vs1.example.com -volume home4 -junction
 Junction Junction
 Vserver Volume Active Junction Path Path Source
----- -----
vs1.example.com home4 true /eng/home RW_volume

```

### Create a qtree

You can create a qtree to contain your data and specify its properties by using the `volume qtree create` command.

#### Before you begin

- The SVM and the volume that will contain the new qtree must already exist.
- The SVM security style must be NTFS, and SMB should be set up and running.

#### Steps

1. Create the qtree: `volume qtree create -vserver vserver_name { -volume volume_name -qtree qtree_name | -qtree-path qtree path } -security-style ntfs`

You can specify the volume and qtree as separate arguments or specify the qtree path argument in the format `/vol/volume_name/_qtree_name`.

2. Verify that the qtree was created with the desired junction path: `volume qtree show -vserver vserver_name { -volume volume_name -qtree qtree_name | -qtree-path qtree path }`

#### Example

The following example creates a qtree named qt01 located on SVM vs1.example.com that has a junction path `/vol/data1`:

```

cluster1::> volume qtree create -vserver vs1.example.com -qtree-path
/vol/data1/qt01 -security-style ntfs
[Job 1642] Job succeeded: Successful

cluster1::> volume qtree show -vserver vs1.example.com -qtree-path
/vol/data1/qt01

 Vserver Name: vs1.example.com
 Volume Name: data1
 Qtree Name: qt01
Actual (Non-Junction) Qtree Path: /vol/data1/qt01
 Security Style: ntfs
 Optrack Mode: enable
 Unix Permissions: ---rwxr-xr-x
 Qtree Id: 2
 Qtree Status: normal
 Export Policy: default
Is Export Policy Inherited: true

```

## Requirements and considerations for creating an SMB share

Before creating an SMB share, you must understand requirements for share paths and share properties, particularly for home directories.

Creating an SMB share entails specifying a directory path structure (using the `-path` option in the `vserver cifs share create` command) that clients will access. The directory path corresponds to the junction path for a volume or qtree that you created in the SVM namespace. The directory path and corresponding junction path must exist before creating your share.

Share paths have the following requirements:

- A directory path name can be up to 255 characters long.
- If there is a space in the path name, the entire string must be put in quotes (for example, `"/new volume/mount here"`).
- If the UNC path (`\servername\sharename\filepath`) of the share contains more than 256 characters (excluding the initial `"\"` in the UNC path), then the **Security** tab in the Windows Properties box is unavailable.

This is a Windows client issue rather than an ONTAP issue. To avoid this issue, do not create shares with UNC paths with more than 256 characters.

Share property defaults can be changed:

- The default initial properties for all shares are `oplocks`, `browsable`, `changenotify`, and `show-previous-versions`.
- It is optional to specify share properties when you create a share.

However, if you do specify share properties when you create the share, the defaults are not used. If you use the `-share-properties` parameter when you create a share, you must specify all of the share properties that you want to apply to the share using a comma-delimited list.

- To designate a home directory share, use the `homedirectory` property.

This feature enables you to configure a share that maps to different directories based on the user that connects to it and a set of variables. Instead of having to create separate shares for each user, you can configure a single share with a few home directory parameters to define a user's relationship between an entry point (the share) and their home directory (a directory on the SVM).

You cannot add or remove this property after creating the share.

Home directory shares have the following requirements:

- Before creating SMB home directories, you must add at least one home directory search path by using the `vserver cifs home-directory search-path add` command.
- Home directory shares specified by the value of `homedirectory` on the `-share-properties` parameter must include the `%w` (Windows user name) dynamic variable in the share name.

The share name can additionally contain the `%d` (domain name) dynamic variable (for example, `%d/%w`) or a static portion in the share name (for example, `home1_%w`).

- If the share is used by administrators or users to connect to other users' home directories (using options to the `vserver cifs home-directory modify` command), the dynamic share name pattern must be preceded by a tilde (~).

[SMB management](#) and [vserver cifs share man](#) pages have additional information.

## Create an SMB share

You must create an SMB share before you can share data from an SMB server with SMB clients. When you create a share, you can set share properties, such as designating the share as a home directory. You can also customize the share by configuring optional settings.

### Before you begin

The directory path for the volume or qtree must exist in the SVM namespace before creating the share.

### About this task

When you create a share, the default share ACL (default share permissions) is Everyone / Full Control. After testing access to the share, you should remove the default share ACL and replace it with a more secure alternative.

### Steps

1. If necessary, create the directory path structure for the share.

The `vserver cifs share create` command checks the path specified in the `-path` option during share creation. If the specified path does not exist, the command fails.

2. Create an SMB share associated with the specified SVM: `vserver cifs share create -vserver`

```
vserver_name -share-name share_name -path path [-share-properties
share_properties,...] [other_attributes] [-comment text]
```

3. Verify that the share was created:vserver cifs share show -share-name share\_name

## Examples

The following command creates an SMB share named “SHARE1” on SVM vs1.example.com. Its directory path is /users, and it is created with default properties.

```
cluster1::> vserver cifs share create -vserver vs1.example.com -share-name
SHARE1 -path /users

cluster1::> vserver cifs share show -share-name SHARE1

Vserver Share Path Properties Comment ACL
----- ----- ----- ----- ----- -----
vs1.example.com SHARE1 /users oplocks - Everyone / Full
Control
 browsable
 changenotify
 show-previous-versions
```

## Verify SMB client access

You should verify that you have configured SMB correctly by accessing and writing data to the share. You should test access using the SMB server name and any NetBIOS aliases.

### Steps

1. Log in to a Windows client.

2. Test access using the SMB server name:

- a. In Windows Explorer, map a drive to the share in the following format: \\SMB\_Server\_Name\Share\_Name

If the mapping is not successful, it is possible that the DNS mapping has not yet propagated throughout the network. You must test access using the SMB server name later.

If the SMB server is named vs1.example.com and the share is named SHARE1, you should enter the following: \\vs0.example.com\SHARE1

- b. On the newly created drive, create a test file, and then delete the file.

You have verified write access to the share using the SMB server name.

3. Repeat Step 2 for any NetBIOS aliases.

## Create SMB share access control lists

Configuring share permissions by creating access control lists (ACLs) for SMB shares enables you to control the level of access to a share for users and groups.

### Before you begin

You must have decided which users or groups will be given access to the share.

### About this task

You can configure share-level ACLs by using local or domain Windows user or group names.

Before creating a new ACL, you should delete the default share ACL Everyone / Full Control, which poses a security risk.

In workgroup mode, the local domain name is the SMB server name.

### Steps

1. Delete the default share ACL:  
`vserver cifs share access-control delete -vserver vserver_name -share share_name -user-or-group everyone`
2. Configure the new ACL:

| If you want to configure ACLs by using a... | Enter the command...                                                                                                                                                                          |
|---------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Windows user                                | <code>vserver cifs share access-control create -vserver vserver_name -share share_name -user-group-type windows -user-or-group Windows_domain_name\\user_name -permission access_right</code> |
| Windows group                               | <code>vserver cifs share access-control create -vserver vserver_name -share share_name -user-group-type windows -user-or-group Windows_group_name -permission access_right</code>             |

3. Verify that the ACL applied to the share is correct by using the `vserver cifs share access-control show` command.

### Example

The following command gives Change permissions to the "Sales Team" Windows group for the "sales" share on the "vs1.example.com`"SVM:

```

cluster1::> vserver cifs share access-control create -vserver
vs1.example.com -share sales -user-or-group "Sales Team" -permission
Change

cluster1::> vserver cifs share access-control show
 Share User/Group User/Group Access
Vserver Name Name Type
Permission

vs1.example.com c$ BUILTIN\Administrators windows
Full_Control
vs1.example.com sales DOMAIN\"Sales Team" windows Change

```

The following commands give Change permission to the local Windows group named “Tiger Team” and Full\_Control permission to the local Windows user named “Sue Chang” for the “datavol5” share on the “vs1” SVM:

```

cluster1::> vserver cifs share access-control create -vserver vs1 -share
datavol5 -user-group-type windows -user-or-group "Tiger Team" -permission
Change

cluster1::> vserver cifs share access-control create -vserver vs1 -share
datavol5 -user-group-type windows -user-or-group "Sue Chang" -permission
Full_Control

cluster1::> vserver cifs share access-control show -vserver vs1
 Share User/Group User/Group Access
Vserver Name Name Type
Permission

vs1 c$ BUILTIN\Administrators windows
Full_Control
vs1 datavol5 DOMAIN\"Tiger Team" windows Change
vs1 datavol5 DOMAIN\"Sue Chang" windows
Full_Control

```

## Configure NTFS file permissions in a share

To enable file access to the users or groups who have access to a share, you must configure NTFS file permissions on files and directories in that share from a Windows client.

### Before you begin

The administrator performing this task must have sufficient NTFS permissions to change permissions on the selected objects.

## About this task

[SMB management](#) and your Windows documentation contain information about how to set standard and advanced NTFS permissions.

## Steps

1. Log in to a Windows client as an administrator.
2. From the **Tools** menu in Windows Explorer, select **Map network drive**.
3. Complete the **Map Network Drive** box:
  - a. Select a **Drive** letter.
  - b. In the **Folder** box, type the SMB server name containing the share that contains the data to which you want to apply permissions and the name of the share.

If your SMB server name is `SMB_SERVER01` and your share is named “`SHARE1`”, you would enter `\SMB_SERVER01\SHARE1`.

You can specify the IP address of the data interface for the SMB server instead of the SMB server name.

- c. Click **Finish**.

The drive you selected is mounted and ready with the Windows Explorer window displaying files and folders contained within the share.

4. Select the file or directory for which you want to set NTFS file permissions.
5. Right-click the file or directory, and then select **Properties**.
6. Select the **Security** tab.

The Security tab displays the list of users and groups for which NTFS permission are set. The Permissions for <Object> box displays a list of Allow and Deny permissions in effect for the selected user or group.

7. Click **Edit**.

The Permissions for <Object> box opens.

8. Perform the desired actions:

| If you want to....                                    | Do the following...                                                                                                                                                                                                                                                                                                    |
|-------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Set standard NTFS permissions for a new user or group | <ol style="list-style-type: none"><li>a. Click <b>Add</b>.<br/>The Select User, Computers, Service Accounts, or Groups window opens.</li><li>b. In the <b>Enter the object names to select</b> box, type the name of the user or group on which you want to add NTFS permission.</li><li>c. Click <b>OK</b>.</li></ol> |

| If you want to....                                              | Do the following...                                                                                |
|-----------------------------------------------------------------|----------------------------------------------------------------------------------------------------|
| Change or remove standard NTFS permissions from a user or group | In the <b>Group or user names</b> box, select the user or group that you want to change or remove. |

9. Perform the desired actions:

| If you want to...                                                 | Do the following                                                                                                                                                                          |
|-------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Set standard NTFS permissions for a new or existing user or group | In the <b>Permissions for &lt;Object&gt;</b> box, select the <b>Allow</b> or <b>Deny</b> boxes for the type of access that you want to allow or not allow for the selected user or group. |
| Remove a user or group                                            | Click <b>Remove</b> .                                                                                                                                                                     |

If some or all of the standard permission boxes are not selectable, it is because the permissions are inherited from the parent object. The **Special permissions** box is not selectable. If it is selected, it means that one or more of the granular advanced rights has been set for the selected user or group.

10. After you finish adding, removing, or editing NTFS permissions on that object, click **OK**.

### Verify user access

You should test that the users you configured can access the SMB share and the files it contains.

#### Steps

1. On a Windows client, log in as one of the users who now has access to the share.
2. From the **Tools** menu in Windows Explorer, select **Map network drive**.
3. Complete the **Map Network Drive** box:
  - a. Select a **Drive** letter.
  - b. In the **Folder** box, type the share name you will provide to users.

If your SMB server name is **SMB\_SERVER01** and your share is named “**SHARE1**”, you would enter **\\\SMB\_SERVER01\share1**.

- c. Click **Finish**.

The drive you selected is mounted and ready with the Windows Explorer window displaying files and folders contained within the share.

4. Create a test file, verify that it exists, write text to it, and then remove the test file.

## Manage SMB with the CLI

## SMB reference overview

ONTAP file access features are available for the SMB protocol. You can enable a CIFS server, create shares, and enable Microsoft services.

SMB (Server Message Block) refers to modern dialects of the Common Internet File System (CIFS) protocol. You will still see CIFS in the ONTAP command-line interface (CLI) and in OnCommand management tools.

You should use these procedures under the following circumstances:

- You want to understand the range of ONTAP SMB protocol capabilities.
- You want to perform less common configuration and maintenance tasks, not basic SMB configuration.
- You want to use the command-line interface (CLI), not System Manager or an automated scripting tool.

## SMB server support

### SMB server support overview

You can enable and configure SMB servers on storage virtual machines (SVMs) to let SMB clients access files on your cluster.

- Each data SVM in the cluster can be bound to exactly one Active Directory domain.
- Data SVMs do not need to be bound to the same domain.
- Multiple SVMs can be bound to the same domain.

You must configure the SVMs and LIFs that you are using to serve data before you can create an SMB server. If your data network is not flat, you might also need to configure IPspaces, broadcast domains, and subnets. The *Network Management Guide* contains details.

### Supported SMB versions and functionality

Server Message Block (SMB) is a remote file-sharing protocol used by Microsoft Windows clients and servers. In ONTAP 9, all SMB versions are supported; however, default SMB 1.0 support depends on your ONTAP version. You should verify that the ONTAP SMB server supports the clients and functionality required in your environment.

The latest information about which SMB clients and domain controllers ONTAP supports is available in the *Interoperability Matrix Tool*.

SMB 2.0 and later versions are enabled by default for ONTAP 9 SMB servers, and can be enabled or disabled as needed. The following table shows SMB 1.0 support and default configuration.

| SMB 1.0 functionality:     |  | In these ONTAP 9 releases: |                               |     |               |
|----------------------------|--|----------------------------|-------------------------------|-----|---------------|
|                            |  | 9.0                        | 9.1                           | 9.2 | 9.3 and later |
| Is enabled by default      |  | Yes                        | Yes                           | Yes | No            |
| Can be enabled or disabled |  | No                         | Yes*9.1 P8 or later required. | Yes | Yes           |

Default settings for SMB 1.0 and 2.0 connections to domain controllers also depend on the ONTAP version. More information is available in the `vserver cifs security modify` man page. For environments with existing CIFS servers running SMB 1.0, you should migrate to a later SMB version as soon as possible to prepare for security and compliance enhancements. Contact your NetApp representative for details.

The following table shows which SMB features are supported in each SMB version. Some SMB features are enabled by default and some require additional configuration.

| This functionality:                   | Requires enablement: | Is supported in ONTAP 9 for these SMB versions: |     |     |     |       |
|---------------------------------------|----------------------|-------------------------------------------------|-----|-----|-----|-------|
|                                       |                      | 1.0                                             | 2.0 | 2.1 | 3.0 | 3.1.1 |
| Legacy SMB 1.0 functionality          |                      | X                                               | X   | X   | X   | X     |
| Durable handles                       |                      |                                                 | X   | X   | X   | X     |
| Compounded operations                 |                      |                                                 | X   | X   | X   | X     |
| Asynchronous operations               |                      |                                                 | X   | X   | X   | X     |
| Increased read and write buffer sizes |                      |                                                 | X   | X   | X   | X     |
| Increased scalability                 |                      |                                                 | X   | X   | X   | X     |
| SMB signing                           | X                    | X                                               | X   | X   | X   | X     |

| <b>This functionality:</b>                              | <b>Requires enablement:</b> | <b>Is supported in ONTAP 9 for these SMB versions:</b> |   |   |   |   |
|---------------------------------------------------------|-----------------------------|--------------------------------------------------------|---|---|---|---|

## Unsupported Windows features

Before you use CIFS in your network, you need to be aware of certain Windows features that ONTAP does not support.

ONTAP does not support the following Windows features:

- Encrypted File System (EFS)
- Logging of NT File System (NTFS) events in the change journal
- Microsoft File Replication Service (FRS)
- Microsoft Windows Indexing Service
- Remote storage through Hierarchical Storage Management (HSM)
- Quota management from Windows clients
- Windows quota semantics
- The LMHOSTS file
- NTFS native compression

## Configure NIS or LDAP name services on the SVM

With SMB access, user mapping to a UNIX user is always performed, even when accessing data in an NTFS security-style volume. If you map Windows users to corresponding UNIX users whose information is stored in NIS or LDAP directory stores, or if you use LDAP for name mapping, you should configure these name services during SMB setup.

### Before you begin

You must have customized your name services database configuration to match your name service infrastructure.

## About this task

SVMs use the name services ns-switch databases to determine the order in which to look up the sources for a given name service database. The ns-switch source can be any combination of “files”, “nis”, or “ldap”. For the groups database, ONTAP attempts to get the group memberships from all configured sources and then uses the consolidated group membership information for access checks. If one of these sources is unavailable at the time of obtaining UNIX group information, ONTAP cannot get the complete UNIX credentials and subsequent access checks might fail. Therefore, you must always check that all ns-switch sources are configured for the group database in the ns-switch settings.

The default is to have the SMB server map all Windows users to the default UNIX user that is stored in the local `passwd` database. If you want to use the default configuration, configuring NIS or LDAP UNIX user and group name services or LDAP user mapping is optional for SMB access.

## Steps

1. If UNIX user, group, and netgroup information is managed by NIS name services, configure NIS name services:
  - a. Determine the current ordering of name services by using the `vserver services name-service ns-switch show` command.

In this example, the three databases (`group`, `passwd`, and `netgroup`) that can use `nis` as a name service source are using only `files` as a source.

```
vserver services name-service ns-switch show -vserver vs1
```

| Vserver | Database | Enabled | Source        |
|---------|----------|---------|---------------|
| vs1     | hosts    | true    | dns,<br>files |
| vs1     | group    | true    | files         |
| vs1     | passwd   | true    | files         |
| vs1     | netgroup | true    | files         |
| vs1     | namemap  | true    | files         |

You must add the `nis` source to the `group` and `passwd` databases, and optionally to the `netgroup` database.

- b. Adjust the name service ns-switch database ordering as desired by using the `vserver services name-service ns-switch modify` command.

For best performance, you should not add a name service to a name service database unless you plan on configuring that name service on the SVM.

If you modify the configuration for more than one name service database, you must run the command separately for each name service database that you want to modify.

In this example, `nis` and `files` are configured as sources for the `group` and `passwd` databases, in

that order. The rest of the name service databases are unchanged.

```
vserver services name-service ns-switch modify -vserver vs1 -database group
-sources nis,files vserver services name-service ns-switch modify -vserver
vs1 -database passwd -sources nis,files
```

- c. Verify that the ordering of name services is correct by using the vserver services name-service ns-switch show command.

```
vserver services name-service ns-switch show -vserver vs1
```

| Vserver | Database | Enabled | Source Order  |
|---------|----------|---------|---------------|
| vs1     | hosts    | true    | dns,<br>files |
| vs1     | group    | true    | nis,<br>files |
| vs1     | passwd   | true    | nis,<br>files |
| vs1     | netgroup | true    | files         |
| vs1     | namemap  | true    | files         |

- d. Create the NIS name service configuration:

```
vserver services name-service nis-domain create -vserver vserver_name
-domain NIS_domain_name -servers NIS_server_IPaddress,... -active true+
```

```
vserver services name-service nis-domain create -vserver vs1 -domain
example.com -servers 10.0.0.60 -active true
```

Beginning with ONTAP 9.2, the field -nis-servers replaces the field -servers. This new field can take either a hostname or an IP address for the NIS server.

- e. Verify that the NIS name service is properly configured and active: vserver services name-service nis-domain show vserver vserver\_name

```
vserver services name-service nis-domain show vserver vs1
```

| Vserver | Domain      | Active Server  |
|---------|-------------|----------------|
| vs1     | example.com | true 10.0.0.60 |

2. If UNIX user, group, and netgroup information or name mapping is managed by LDAP name services, configure LDAP name services by using the information located [NFS management](#).

## How ONTAP name service switch configuration works

ONTAP stores name service configuration information in a table that is the equivalent of the `/etc/nsswitch.conf` file on UNIX systems. You must understand the function of the table and how ONTAP uses it so that you can configure it appropriately for your environment.

The ONTAP name service switch table determines which name service sources ONTAP consults in which order to retrieve information for a certain type of name service information. ONTAP maintains a separate name service switch table for each SVM.

### Database types

The table stores a separate name service list for each of the following database types:

| Database type | Defines name service sources for...   | Valid sources are... |
|---------------|---------------------------------------|----------------------|
| hosts         | Converting host names to IP addresses | files, dns           |
| group         | Looking up user group information     | files, nis, ldap     |
| passwd        | Looking up user information           | files, nis, ldap     |
| netgroup      | Looking up netgroup information       | files, nis, ldap     |
| namemap       | Mapping user names                    | files, ldap          |

### Source types

The sources specify which name service source to use for retrieving the appropriate information.

| Specify source type... | To look up information in...                                                 | Managed by the command families...                                                                                                                                    |
|------------------------|------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| files                  | Local source files                                                           | vserver services name-service unix-user vserver services name-service unix-group<br>vserver services name-service netgroup<br>vserver services name-service dns hosts |
| nis                    | External NIS servers as specified in the NIS domain configuration of the SVM | vserver services name-service nis-domain                                                                                                                              |

| Specify source type... | To look up information in...                                                   | Managed by the command families... |
|------------------------|--------------------------------------------------------------------------------|------------------------------------|
| ldap                   | External LDAP servers as specified in the LDAP client configuration of the SVM | vserver services name-service ldap |
| dns                    | External DNS servers as specified in the DNS configuration of the SVM          | vserver services name-service dns  |

Even if you plan to use NIS or LDAP for both data access and SVM administration authentication, you should still include `files` and configure local users as a fallback in case NIS or LDAP authentication fails.

#### Protocols used to access external sources

To access the servers for external sources, ONTAP uses the following protocols:

| External name service source | Protocol used for access |
|------------------------------|--------------------------|
| NIS                          | UDP                      |
| DNS                          | UDP                      |
| LDAP                         | TCP                      |

#### Example

The following example displays the name service switch configuration for the SVM `svm_1`:

```
cluster1::>*> vserver services name-service ns-switch show -vserver svm_1
 Source
Vserver Database Order

svm_1 hosts files,
 dns
svm_1 group files
svm_1 passwd files
svm_1 netgroup nis,
 files
```

To look up user or group information, ONTAP consults only local sources `files`. If the query does not return any results, the lookup fails.

To look up netgroup information, ONTAP first consults external NIS servers. If the query does not return any results, the local netgroup file is checked next.

There are no name service entries for name mapping in the table for the SVM `svm_1`. Therefore, ONTAP consults only local source `files` by default.

## Manage SMB servers

### Modify SMB servers

You can move a SMB server from a workgroup to an Active Directory domain, from a workgroup to another workgroup, or from an Active Directory domain to a workgroup by using the `vserver cifs modify` command.

#### About this task

You can also modify other attributes of the SMB server, such as the SMB server name and administrative status. See the man page for details.

#### Choices

- Move the SMB server from a workgroup to an Active Directory domain:

- Set the administrative status of the SMB server to `down`.

```
Cluster1::>vserver cifs modify -vserver vs1 -status-admin down
```

- Move the SMB server from the workgroup to an Active Directory domain: `vserver cifs modify -vserver vserver_name -domain domain_name`

```
Cluster1::>vserver cifs modify -vserver vs1 -domain example.com
```

In order to create an Active Directory machine account for the SMB server, you must supply the name and password of a Windows account with sufficient privileges to add computers to the `ou=example` container within the `example.com` domain.

Beginning with ONTAP 9.7, your AD administrator can provide you with a URI to a keytab file as an alternative to providing you with a name and password to a privileged Windows account. When you receive the URI, include it in the `-keytab-uri` parameter with the `vserver cifs` commands.

- Move the SMB server from a workgroup to another workgroup:

- Set the administrative status of the SMB server to `down`.

```
Cluster1::>vserver cifs modify -vserver vs1 -status-admin down
```

- Modify the workgroup for the SMB server: `vserver cifs modify -vserver vserver_name -workgroup new_workgroup_name`

```
Cluster1::>vserver cifs modify -vserver vs1 -workgroup workgroup2
```

- Move the SMB server from an Active Directory domain to a workgroup:

- Set the administrative status of the SMB server to `down`.

```
Cluster1::>vserver cifs modify -vserver vs1 -status-admin down
```

- b. Move the SMB server from the Active Directory domain to a workgroup: `vserver cifs modify -vserver vserver_name -workgroup workgroup_name`

```
cluster1::> vserver cifs modify -vserver vs1 -workgroup workgroup1
```

To enter workgroup mode, all domain-based features must be disabled and their configuration removed automatically by the system, including continuously-available shares, shadow copies, and AES. However, domain-configured share ACLs such as "EXAMPLE.COM\userName" will not work properly, but cannot be removed by ONTAP. Remove these share ACLs as soon as possible using external tools after the command completes. If AES is enabled, you may be asked to supply the name and password of a Windows account with sufficient privileges to disable it in the "EXAMPLE.COM" domain.

- Modify other attributes by using the appropriate parameter of the `vserver cifs modify` command.

## Use options to customize SMB servers

### Available SMB server options

It is useful to know what options are available when considering how to customize the SMB server. Although some options are for general use on the SMB server, several are used to enable and configure specific SMB functionality. SMB server options are controlled with the `vserver cifs options modify` option.

The following list specifies the SMB server options that are available at the admin privilege level:

- **Configuring the SMB session timeout value**

Configuring this option enables you to specify the number of seconds of idle time before an SMB session is disconnected. An idle session is a session in which a user does not have any files or directories opened on the client. The default value is 900 seconds.

- **Configuring the default UNIX user**

Configuring this option enables you to specify the default UNIX user that the SMB server uses. ONTAP automatically creates a default user named "pcuser" (with a UID of 65534), creates a group named "pcuser" (with a GID of 65534), and adds the default user to the "pcuser" group. When you create a SMB server, ONTAP automatically configures "pcuser" as the default UNIX user.

- **Configuring the guest UNIX user**

Configuring this option enables you to specify the name of a UNIX user to which users who log in from untrusted domains are mapped, which allows a user from an untrusted domain to connect to the SMB server. By default, this option is not configured (there is no default value); therefore, the default is to not allow users from untrusted domains to connect to the SMB server.

- **Enabling or disabling read grant execution for mode bits**

Enabling or disabling this option enables you to specify whether to allow SMB clients to run executable files with UNIX mode bits to which they have read access, even when the UNIX executable bit is not set. This option is disabled by default.

- **Enabling or disabling the ability to delete read-only files from NFS clients**

Enabling or disabling this option determines whether to allow NFS clients to delete files or folders with the read-only attribute set. NTFS delete semantics does not allow the deletion of a file or folder when the read-only attribute is set. UNIX delete semantics ignores the read-only bit, using the parent directory permissions instead to determine whether a file or folder can be deleted. The default setting is disabled, which results in NTFS delete semantics.

- **Configuring Windows Internet Name Service server addresses**

Configuring this option enables you to specify a list of Windows Internet Name Service (WINS) server addresses as a comma-delimited list. You must specify IPv4 addresses. IPv6 addresses are not supported. There is no default value.

The following list specifies the SMB server options that are available at the advanced privilege level:

- **Granting UNIX group permissions to CIFS users**

Configuring this option determines whether the incoming CIFS user who is not the owner of the file can be granted the group permission. If the CIFS user is not the owner of the UNIX security-style file and this parameter is set to `true`, then the group permission is granted for the file. If the CIFS user is not the owner of the UNIX security-style file and this parameter is set to `false`, then the normal UNIX rules are applicable to grant the file permission. This parameter is applicable to UNIX security-style files that have permission set as `mode bits` and is not applicable to files with the NTFS or NFSv4 security mode. The default setting is `false`.

- **Enabling or disabling SMB 1.0**

SMB 1.0 is disabled by default on an SVM for which a SMB server is created in ONTAP 9.3.

Beginning ONTAP 9.3, SMB 1.0 is disabled by default for new SMB servers created in ONTAP 9.3. You should migrate to a later SMB version as soon as possible to prepare for security and compliance enhancements. Contact your NetApp representative for details.

- **Enabling or disabling SMB 2.x**

SMB 2.0 is the minimum SMB version that supports LIF failover. If you disable SMB 2.x, ONTAP also automatically disables SMB 3.X.

SMB 2.0 is supported only on SVMs. The option is enabled by default on SVMs

- **Enabling or disabling SMB 3.0**

SMB 3.0 is the minimum SMB version that supports continuously available shares. Windows Server 2012 and Windows 8 are the minimum Windows versions that support SMB 3.0.

SMB 3.0 is supported only on SVMs. The option is enabled by default on SVMs

- **Enabling or disabling SMB 3.1**

Windows 10 is the only Windows version that supports SMB 3.1.

SMB 3.1 is supported only on SVMs. The option is enabled by default on SVMs

- **Enabling or disabling ODX copy offload**

ODX copy offload is used automatically by Windows clients that support it. This option is enabled by default.

- **Enabling or disabling the direct-copy mechanism for ODX copy offload**

The direct-copy mechanism increases the performance of the copy offload operation when Windows clients try to open the source file of a copy in a mode that prevents the file being changed while the copy is in progress. By default, the direct copy mechanism is enabled.

- **Enabling or disabling automatic node referrals**

With automatic node referrals, the SMB server automatically refers clients to a data LIF local to the node that hosts the data accessed through the requested share.

- **Enabling or disabling export policies for SMB**

This option is disabled by default.

- **Enabling or disabling using junction points as reparse points**

If this option is enabled, the SMB server exposes junction points to SMB clients as reparse points. This option is valid only for SMB 2.x or SMB 3.0 connections. This option is enabled by default.

This option is supported only on SVMs. The option is enabled by default on SVMs

- **Configuring the number of maximum simultaneous operations per TCP connection**

The default value is 255.

- **Enabling or disabling local Windows users and groups functionality**

This option is enabled by default.

- **Enabling or disabling local Windows users authentication**

This option is enabled by default.

- **Enabling or disabling VSS shadow copy functionality**

ONTAP uses the shadow copy functionality to perform remote backups of data stored using the Hyper-V over SMB solution.

This option is supported only on SVMs, and only for Hyper-V over SMB configurations. The option is enabled by default on SVMs

- **Configuring the shadow copy directory depth**

Configuring this option enables you to define the maximum depth of directories on which to create shadow

copies when using the shadow copy functionality.

This option is supported only on SVMs, and only for Hyper-V over SMB configurations. The option is enabled by default on SVMs

- **Enabling or disabling multidomain search capabilities for name mapping**

If enabled, when a UNIX user is mapped to a Windows domain user by using a wildcard (\*) in the domain portion of the Windows user name (for example, \*\joe), ONTAP searches for the specified user in all of the domains with bidirectional trusts to the home domain. The home domain is the domain that contains the SMB server's computer account.

As an alternative to searching all of the bidirectionally trusted domains, you can configure a list of preferred trusted domains. If this option is enabled and a preferred list is configured, the preferred list is used to perform multidomain name mapping searches.

The default is to enable multidomain name mapping searches.

- **Configuring the file system sector size**

Configuring this option enables you to configure the file system sector size in bytes that ONTAP reports to SMB clients. There are two valid values for this option: 4096 and 512. The default value is 4096. You might need to set this value to 512 if the Windows application supports only a sector size of 512 bytes.

- **Enabling or disabling Dynamic Access Control**

Enabling this option enables you to secure objects on the SMB server by using Dynamic Access Control (DAC), including using auditing to stage central access policies and using Group Policy Objects to implement central access policies. The option is disabled by default.

This option is supported only on SVMs.

- **Setting the access restrictions for non-authenticated sessions (restrict anonymous)**

Setting this option determines what the access restrictions are for non-authenticated sessions. The restrictions are applied to anonymous users. By default, there are no access restrictions for anonymous users.

- **Enabling or disabling the presentation of NTFS ACLs on volumes with UNIX effective security (UNIX security-style volumes or mixed security-style volumes with UNIX effective security)**

Enabling or disabling this option determines how file security on files and folders with UNIX security is presented to SMB clients. If enabled, ONTAP presents files and folders in volumes with UNIX security to SMB clients as having NTFS file security with NTFS ACLs. If disabled, ONTAP presents volumes with UNIX security as FAT volumes, with no file security. By default, volumes are presented as having NTFS file security with NTFS ACLs.

- **Enabling or disabling the SMB fake open functionality**

Enabling this functionality improves SMB 2.x and SMB 3.0 performance by optimizing how ONTAP makes open and close requests when querying for attribute information on files and directories. By default, the SMB fake open functionality is enabled. This option is useful only for connections that are made with SMB 2.x or later.

- **Enabling or disabling the UNIX extensions**

Enabling this option enables UNIX extensions on a SMB server. UNIX extensions allow POSIX/UNIX style security to be displayed through the SMB protocol. By default this option is disabled.

If you have UNIX-based SMB clients, such as Mac OSX clients, in your environment, you should enable UNIX extensions. Enabling UNIX extensions allows the SMB server to transmit POSIX/UNIX security information over SMB to the UNIX-based client, which then translates the security information into POSIX/UNIX security.

- **Enabling or disabling support for short name searches**

Enabling this option allows the SMB server to perform searches on short names. A search query with this option enabled tries to match 8.3 file names along with long file names. The default value for this parameter is `false`.

- **Enabling or disabling support for automatic advertisement of DFS capabilities**

Enabling or disabling this option determines whether SMB servers automatically advertise DFS capabilities to SMB 2.x and SMB 3.0 clients that connect to shares. ONTAP uses DFS referrals in the implementation of symbolic links for SMB access. If enabled, the SMB server always advertises DFS capabilities regardless of whether symbolic link access is enabled. If disabled, the SMB server advertises DFS capabilities only when the clients connect to shares where symbolic link access is enabled.

- **Configuring the maximum number of SMB credits**

Beginning with ONTAP 9.4, configuring the `-max-credits` option allows you to limit the number of credits to be granted on an SMB connection when clients and server are running SMB version 2 or later. The default value is 128.

- **Enabling or disabling support for SMB Multichannel**

Enabling the `-is-multichannel-enabled` option in ONTAP 9.4 and later releases allows the SMB server to establish multiple connections for a single SMB session when appropriate NICs are deployed on the cluster and its clients. Doing so improves throughput and fault tolerance. The default value for this parameter is `false`.

When SMB Multichannel is enabled, you can also specify the following parameters:

- The maximum number of connections allowed per Multichannel session. The default value for this parameter is 32.
- The maximum number of network interfaces advertised per Multichannel session. The default value for this parameter is 256.

## Configuring SMB server options

You can configure SMB server options at any time after you have created a SMB server on a storage virtual machine (SVM).

### Step

1. Perform the desired action:

| If you want to configure SMB server options... | Enter the command...                                                                                                                                                                                                       |
|------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| At admin-privilege level                       | <code>vserver cifs options modify -vserver vserver_name options</code>                                                                                                                                                     |
| At advanced-privilege level                    | <ul style="list-style-type: none"> <li>a. <code>set -privilege advanced</code></li> <li>b. <code>vserver cifs options modify -vserver vserver_name options</code></li> <li>c. <code>set -privilege admin</code></li> </ul> |

For more information about configuring SMB server options, see the man page for the `vserver cifs options modify` command.

#### Configure the grant UNIX group permission to SMB users

You can configure this option to grant group permissions to access files or directories even if the incoming SMB user is not the owner of the file.

##### Steps

1. Set the privilege level to advanced: `set -privilege advanced`
2. Configure the grant UNIX group permission as appropriate:

| If you want to                                                                                                        | Enter the command                                                                |
|-----------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------|
| Enable the access to the files or directories to get group permissions even if the user is not the owner of the file  | <code>vserver cifs options modify -grant-unix-group-perms-to-others true</code>  |
| Disable the access to the files or directories to get group permissions even if the user is not the owner of the file | <code>vserver cifs options modify -grant-unix-group-perms-to-others false</code> |

3. Verify that the option is set to the desired value: `vserver cifs options show -fields grant-unix-group-perms-to-others`
4. Return to the admin privilege level: `set -privilege admin`

#### Configure access restrictions for anonymous users

By default, an anonymous, unauthenticated user (also known as the *null user*) can access certain information on the network. You can use a SMB server option to configure access restrictions for the anonymous user.

##### About this task

The `-restrict-anonymous` SMB server option corresponds to the `RestrictAnonymous` registry entry in Windows.

Anonymous users can list or enumerate certain types of system information from Windows hosts on the

network, including user names and details, account policies, and share names. You can control access for the anonymous user by specifying one of three access restriction settings:

| Value                    | Description                                                        |
|--------------------------|--------------------------------------------------------------------|
| no-restriction (default) | Specifies no access restrictions for anonymous users.              |
| no-enumeration           | Specifies that only enumeration is restricted for anonymous users. |
| no-access                | Specifies that access is restricted for anonymous users.           |

## Steps

1. Set the privilege level to advanced: `set -privilege advanced`
2. Configure the restrict anonymous setting: `vserver cifs options modify -vserver vserver_name -restrict-anonymous {no-restriction|no-enumeration|no-access}`
3. Verify that the option is set to the desired value: `vserver cifs options show -vserver vserver_name`
4. Return to the admin privilege level: `set -privilege admin`

### [Available SMB server options](#)

## **Manage how file security is presented to SMB clients for UNIX security-style data**

### **Manage how file security is presented to SMB clients for UNIX security-style data overview**

You can choose how you want to present file security to SMB clients for UNIX security-style data by enabling or disabling the presentation of NTFS ACLs to SMB clients. There are advantages with each setting, which you should understand to choose the setting best suited for your business requirements.

By default, ONTAP presents UNIX permissions on UNIX security-style volumes to SMB clients as NTFS ACLs. There are scenarios where this is desirable, including the following:

- You want to view and edit UNIX permissions by using the **Security** tab in the Windows Properties box.

You cannot modify permissions from a Windows client if the operation is not permitted by the UNIX system. For example, you cannot change the ownership of a file you do not own, because the UNIX system does not permit this operation. This restriction prevents SMB clients from bypassing UNIX permissions set on the files and folders.
- Users are editing and saving files on the UNIX security-style volume by using certain Windows applications, for example Microsoft Office, where ONTAP must preserve UNIX permissions during save operations.
- There are certain Windows applications in your environment that expect to read NTFS ACLs on files they use.

Under certain circumstances, you might want to disable the presentation of UNIX permissions as NTFS ACLs. If this functionality is disabled, ONTAP presents UNIX security-style volumes as FAT volumes to SMB clients. There are specific reasons why you might want to present UNIX security-style volumes as FAT volumes to SMB clients:

- You only change UNIX permissions by using mounts on UNIX clients.

The Security tab is not available when a UNIX security-style volume is mapped on an SMB client. The mapped drive appears to be formatted with the FAT file system, which has no file permissions.

- You are using applications over SMB that set NTFS ACLs on accessed files and folders, which can fail if the data resides on UNIX security-style volumes.

If ONTAP reports the volume as FAT, the application does not try to change an ACL.

## Enable or disable the presentation of NTFS ACLs for UNIX security-style data

You can enable or disable the presentation of NTFS ACLs to SMB clients for UNIX security-style data (UNIX security-style volumes and mixed security-style volumes with UNIX effective security).

### About this task

If you enable this option, ONTAP presents files and folders on volumes with effective UNIX security style to SMB clients as having NTFS ACLs. If you disable this option, the volumes are presented as FAT volumes to SMB clients. The default is to present NTFS ACLs to SMB clients.

### Steps

1. Set the privilege level to advanced: `set -privilege advanced`
2. Configure the UNIX NTFS ACL option setting: `vserver cifs options modify -vserver vserver_name -is-unix-nt-acl-enabled {true|false}`
3. Verify that the option is set to the desired value: `vserver cifs options show -vserver vserver_name`
4. Return to the admin privilege level: `set -privilege admin`

## How ONTAP preserves UNIX permissions

When files in a FlexVol volume that currently have UNIX permissions are edited and saved by Windows applications, ONTAP can preserve the UNIX permissions.

When applications on Windows clients edit and save files, they read the security properties of the file, create a new temporary file, apply those properties to the temporary file, and then give the temporary file the original file name.

When Windows clients perform a query for the security properties, they receive a constructed ACL that exactly represents the UNIX permissions. The sole purpose of this constructed ACL is to preserve the file's UNIX permissions as files are updated by Windows applications to ensure that the resulting files have the same

UNIX permissions. ONTAP does not set any NTFS ACLs using the constructed ACL.

## Manage UNIX permissions using the Windows Security tab

If you want to manipulate UNIX permissions of files or folders in mixed security-style volumes or qtrees on SVMs, you can use the Security tab on Windows clients. Alternatively, you can use applications that can query and set Windows ACLs.

- Modifying UNIX permissions

You can use the Windows Security tab to view and change UNIX permissions for a mixed security-style volume or qtree. If you use the main Windows Security tab to change UNIX permissions, you must first remove the existing ACE you want to edit (this sets the mode bits to 0) before you make your changes. Alternatively, you can use the Advanced editor to change permissions.

If mode permissions are used, you can directly change the mode permissions for the listed UID, GID, and others (everyone else with an account on the computer). For example, if the displayed UID has r-x permissions, you can change the UID permissions to rwx.

- Changing UNIX permissions to NTFS permissions

You can use the Windows Security tab to replace UNIX security objects with Windows security objects on a mixed security-style volume or qtree where the files and folders have a UNIX effective security style.

You must first remove all listed UNIX permission entries before you can replace them with the desired Windows User and Group objects. You can then configure NTFS-based ACLs on the Windows User and Group objects. By removing all UNIX security objects and adding only Windows Users and Groups to a file or folder in a mixed security-style volume or qtree, you change the effective security style on the file or folder from UNIX to NTFS.

When changing permissions on a folder, the default Windows behavior is to propagate these changes to all subfolders and files. Therefore, you must change the propagation choice to the desired setting if you do not want to propagate a change in security style to all child folders, subfolders, and files.

## Manage SMB server security settings

### How ONTAP handles SMB client authentication

Before users can create SMB connections to access data contained on the SVM, they must be authenticated by the domain to which the SMB server belongs. The SMB server supports two authentication methods, Kerberos and NTLM (NTLMv1 or NTLMv2). Kerberos is the default method used to authenticate domain users.

### Kerberos authentication

ONTAP supports Kerberos authentication when creating authenticated SMB sessions.

Kerberos is the primary authentication service for Active Directory. The Kerberos server, or Kerberos Key Distribution Center (KDC) service, stores and retrieves information about security principles in the Active Directory. Unlike the NTLM model, Active Directory clients who want to establish a session with another computer, such the SMB server, contact a KDC directly to obtain their session credentials.

## NTLM authentication

NTLM client authentication is done using a challenge response protocol based on shared knowledge of a user-specific secret based on a password.

If a user creates an SMB connection using a local Windows user account, authentication is done locally by the SMB server using NTLMv2.

### Guidelines for SMB server security settings in an SVM disaster recovery configuration

Before creating an SVM that is configured as a disaster recovery destination where the identity is not preserved (the `-identity-preserve` option is set to `false` in the SnapMirror configuration), you should know about how SMB server security settings are managed on the destination SVM.

- Non-default SMB server security settings are not replicated to the destination.

When you create a SMB server on the destination SVM, all SMB server security settings are set to default values. When the SVM disaster recovery destination is initialized, updated, or resynced, the SMB server security settings on the source are not replicated to the destination.

- You must manually configure non-default SMB server security settings.

If you have non-default SMB server security settings configured on the source SVM, you must manually configure these same settings on the destination SVM after the destination becomes read-write (after the SnapMirror relationship is broken).

### Display information about SMB server security settings

You can display information about SMB server security settings on your storage virtual machines (SVMs). You can use this information to verify that the security settings are correct.

#### About this task

A displayed security setting can be the default value for that object or a non-default value that is configured either by using the ONTAP CLI or by using Active Directory group policy objects (GPOs).

Do not use the `vserver cifs security show` command for SMB servers in workgroup mode, because some of the options are not valid.

#### Step

1. Perform one of the following actions:

| If you want display information about... | Enter the command...                                                 |
|------------------------------------------|----------------------------------------------------------------------|
| All security settings on a specified SVM | <code>vserver cifs security show -vserver <i>vserver_name</i></code> |

| If you want display information about...           | Enter the command...                                                                                                                          |
|----------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------|
| A specific security setting or settings on the SVM | vserver cifs security show -vserver<br>_vserver_name_-fields [fieldname,...]<br>You can enter -fields ? to determine what fields you can use. |

## Example

The following example shows all security settings for SVM vs1:

```
cluster1::> vserver cifs security show -vserver vs1

Vserver: vs1

 Kerberos Clock Skew: 5 minutes
 Kerberos Ticket Age: 10 hours
 Kerberos Renewal Age: 7 days
 Kerberos KDC Timeout: 3 seconds
 Is Signing Required: false
 Is Password Complexity Required: true
 Use start_tls For AD LDAP connection: false
 Is AES Encryption Enabled: false
 LM Compatibility Level: lm-ntlm-ntlmv2-krb
 Is SMB Encryption Required: false
 Client Session Security: none
 SMB1 Enabled for DC Connections: false
 SMB2 Enabled for DC Connections: system-default
LDAP Referral Enabled For AD LDAP connections: false
 Use LDAPS for AD LDAP connection: false
Encryption is required for DC Connections: false
AES session key enabled for NetLogon channel: false
Try Channel Binding For AD LDAP Connections: false
```

Note that the settings displayed depend on the running ONTAP version.

The following example shows the Kerberos clock skew for SVM vs1:

```
cluster1::> vserver cifs security show -vserver vs1 -fields kerberos-
clock-skew

 vserver kerberos-clock-skew

vs1 5
```

## Related information

## Displaying information about GPO configurations

### Enable or disable required password complexity for local SMB users

Required password complexity provides enhanced security for local SMB users on your storage virtual machines (SVMs). The required password complexity feature is enabled by default. You can disable it and reenable it at any time.

#### Before you begin

Local users, local groups, and local user authentication must be enabled on the CIFS server.

#### About this task

You must not use the `vserver cifs security modify` command for a CIFS server in workgroup mode because some of the options are not valid.

#### Steps

1. Perform one of the following actions:

| If you want required password complexity for local SMB users to be... | Enter the command...                                                                                   |
|-----------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------|
| Enabled                                                               | <code>vserver cifs security modify -vserver vserver_name -is-password-complexity-required true</code>  |
| Disabled                                                              | <code>vserver cifs security modify -vserver vserver_name -is-password-complexity-required false</code> |

2. Verify the security setting for required password complexity: `vserver cifs security show -vserver vserver_name`

#### Example

The following example shows that required password complexity is enabled for local SMB users for SVM vs1:

```
cluster1::> vserver cifs security modify -vserver vs1 -is-password-complexity-required true

cluster1::> vserver cifs security show -vserver vs1 -fields is-password-complexity-required
vserver is-password-complexity-required

vs1 true
```

#### Related information

## Using local users and groups for authentication and authorization

### Requirements for local user passwords

#### Changing local user account passwords

##### Modify the CIFS server Kerberos security settings

You can modify certain CIFS server Kerberos security settings, including the maximum allowed Kerberos clock skew time, the Kerberos ticket lifetime, and the maximum number of ticket renewal days.

##### About this task

Modifying CIFS server Kerberos settings by using the `vserver cifs security modify` command modifies the settings only on the single storage virtual machine (SVM) that you specify with the `-vserver` parameter. You can centrally manage Kerberos security settings for all SVMs on the cluster belonging to the same Active Directory domain by using Active Directory group policy objects (GPOs).

##### Steps

1. Perform one or more of the following actions:

| If you want to...                                                                       | Enter...                                                                                                                                          |
|-----------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------|
| Specify the maximum allowed Kerberos clock skew time in minutes.                        | <code>vserver cifs security modify -vserver vserver_name -kerberos-clock-skew integer_in_minutes</code><br><br>The default setting is 5 minutes.  |
| Specify the Kerberos ticket lifetime in hours.                                          | <code>vserver cifs security modify -vserver vserver_name -kerberos-ticket-age integer_in_hours</code><br><br>The default setting is 10 hours.     |
| Specify the maximum number of ticket renewal days.                                      | <code>vserver cifs security modify -vserver vserver_name -kerberos-renew-age integer_in_days</code><br><br>The default setting is 7 days.         |
| Specify the timeout for sockets on KDCs after which all KDCs are marked as unreachable. | <code>vserver cifs security modify -vserver vserver_name -kerberos-kdc-timeout integer_in_seconds</code><br><br>The default setting is 3 seconds. |

2. Verify the Kerberos security settings:

```
vserver cifs security show -vserver vserver_name
```

## Example

The following example makes the following changes to Kerberos security: "Kerberos Clock Skew" is set to 3 minutes and "Kerberos Ticket Age" is set to 8 hours for SVM vs1:

```
cluster1::> vserver cifs security modify -vserver vs1 -kerberos-clock-skew
3 -kerberos-ticket-age 8

cluster1::> vserver cifs security show -vserver vs1

Vserver: vs1

 Kerberos Clock Skew: 3 minutes
 Kerberos Ticket Age: 8 hours
 Kerberos Renewal Age: 7 days
 Kerberos KDC Timeout: 3 seconds
 Is Signing Required: false
 Is Password Complexity Required: true
 Use start_tls For AD LDAP connection: false
 Is AES Encryption Enabled: false
 LM Compatibility Level: lm-ntlm-ntlmv2-krb
 Is SMB Encryption Required: false
```

### Set the SMB server minimum authentication security level

You can set the SMB server minimum security level, also known as the *LMCompatibilityLevel*, on your SMB server to meet your business security requirements for SMB client access. The minimum security level is the minimum level of the security tokens that the SMB server accepts from SMB clients.

#### About this task

- SMB servers in workgroup mode support only NTLM authentication. Kerberos authentication is not supported.
- LMCompatibilityLevel applies only to SMB client authentication, not admin authentication.

You can set the minimum authentication security level to one of four supported security levels.

| Value                        | Description                                                                                                |
|------------------------------|------------------------------------------------------------------------------------------------------------|
| lm-ntlm-ntlmv2-krb (default) | The storage virtual machine (SVM) accepts LM, NTLM, NTLMv2, and Kerberos authentication security.          |
| ntlm-ntlmv2-krb              | The SVM accepts NTLM, NTLMv2, and Kerberos authentication security. The SVM denies LM authentication.      |
| ntlmv2-krb                   | The SVM accepts NTLMv2 and Kerberos authentication security. The SVM denies LM and NTLM authentication.    |
| krb                          | The SVM accepts Kerberos authentication security only. The SVM denies LM, NTLM, and NTLMv2 authentication. |

## Steps

1. Set the minimum authentication security level: `vserver cifs security modify -vserver vserver_name -lm-compatibility-level {lm-ntlm-ntlmv2-krb|ntlm-ntlmv2-krb|ntlmv2-krb|krb}`
2. Verify that the authentication security level is set to the desired level: `vserver cifs security show -vserver vserver_name`

## Related information

[Enabling or disabling AES encryption for Kerberos-based communication](#)

### Configure strong security for Kerberos-based communication by using AES encryption

For strongest security with Kerberos-based communication, you can enable AES-256 and AES-128 encryption on the SMB server. By default, when you create a SMB server on the SVM, Advanced Encryption Standard (AES) encryption is disabled. You must enable it to take advantage of the strong security provided by AES encryption.

Kerberos-related communication for SMB is used during SMB server creation on the SVM, as well as during the SMB session setup phase. The SMB server supports the following encryption types for Kerberos communication:

- AES 256
- AES 128
- DES
- RC4-HMAC

If you want to use the highest security encryption type for Kerberos communication, you should enable AES encryption for Kerberos communication on the SVM.

When the SMB server is created, the domain controller creates a computer machine account in Active Directory. At this time, the KDC becomes aware of the encryption capabilities of the particular machine

account. Subsequently, a particular encryption type is selected for encrypting the service ticket that the client presents to the server during authentication.

Beginning with ONTAP 9.12.1, you can specify which encryption types to advertise to the Active Directory (AD) KDC. You can use the `-advertised-enc-types` option to enable recommended encryption types, and you can use it to disable weaker encryption types. Learn how to [enable and disable encryption types for Kerberos-based communication](#).

Intel AES New Instructions (Intel AES NI) is available in SMB 3.0, improving on the AES algorithm and accelerating data encryption with supported processor families. Beginning with SMB 3.1.1, AES-128-GCM replaces AES-128-CCM as the hash algorithm used by SMB encryption.

## Related information

[Modifying the CIFS server Kerberos security settings](#)

[Enable or disable AES encryption for Kerberos-based communication](#)

To take advantage of the strongest security with Kerberos-based communication, you can enable AES-256 and AES-128 encryption on the SMB server. If you do not want the SMB server to select the AES encryption types for Kerberos-based communication with the Active Directory (AD) KDC, you can disable AES encryption. By default, AES encryption is disabled.

## About this task

Beginning with ONTAP 9.12.1, AES encryption is enabled and disabled using the `-advertised-enc-types` option, which allows you to specify the encryption types advertised to the AD KDC. The default setting is `rc4` and `des`, but when an AES type is specified, AES encryption is enabled. You can also use the option to explicitly disable the weaker RC4 and DES encryption types. In earlier ONTAP releases, you must use the `-is-aes-encryption-enabled` option to enable and disable AES encryption, and encryption types cannot be specified.

To enhance security, the storage virtual machine (SVM) changes its machine account password in the AD each time the AES security option is modified. Changing the password might require administrative AD credentials for the organizational unit (OU) that contains the machine account.

If an SVM is configured as a disaster recovery destination where the identity is not preserved (the `-identity-preserve` option is set to `false` in the SnapMirror configuration), the non-default SMB server security settings are not replicated to the destination. If you have enabled AES encryption on the source SVM, you must manually enable it on the destination SVM after the destination becomes read-write (after the SnapMirror relationship is broken).

## Example 1. Steps

### ONTAP 9.12.1 and later

1. Perform one of the following actions:

| If you want the AES encryption types for Kerberos communication to be... | Enter the command...                                                                            |
|--------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------|
| Enabled                                                                  | vserver cifs security modify<br>-vserver vserver_name -advertised<br>-enc-types aes-128,aes-256 |
| Disabled                                                                 | vserver cifs security modify<br>-vserver vserver_name -advertised<br>-enc-types des,rc4         |

**Note:** The `-is-aes-encryption-enabled` option is deprecated in ONTAP 9.12.1 and might be removed in a later release.

2. Verify that AES encryption is enabled or disabled as desired: `vserver cifs security show -vserver vserver_name -fields advertised-enc-types`

### Examples

The following example enables the AES encryption types for the SMB server on SVM vs1:

```
cluster1::> vserver cifs security modify -vserver vs1 -advertised-enc
-types aes-128,aes-256

cluster1::> vserver cifs security show -vserver vs1 -fields advertised-
enc-types

vserver advertised-enc-types

vs1 aes-128,aes-256
```

The following example enables the AES encryption types for the SMB server on SVM vs2. The administrator is prompted to enter the administrative AD credentials for the OU containing the SMB server.

```
cluster1::> vserver cifs security modify -vserver vs2 -advertised-enc-types aes-128,aes-256
```

Info: In order to enable SMB AES encryption, the password for the SMB server

machine account must be reset. Enter the username and password for the SMB domain "EXAMPLE.COM".

Enter your user ID: administrator

Enter your password:

```
cluster1::> vserver cifs security show -vserver vs2 -fields advertised-enc-types
```

```
vserver advertised-enc-types

vs2 aes-128,aes-256
```

### ONTAP 9.11.1 and earlier

1. Perform one of the following actions:

| If you want the AES encryption types for Kerberos communication to be... | Enter the command...                                                                                    |
|--------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------|
| Enabled                                                                  | <pre>vserver cifs security modify<br/>-vserver vserver_name -is-aes<br/>-encryption-enabled true</pre>  |
| Disabled                                                                 | <pre>vserver cifs security modify<br/>-vserver vserver_name -is-aes<br/>-encryption-enabled false</pre> |

2. Verify that AES encryption is enabled or disabled as desired: 

```
vserver cifs security show
-vserver vserver_name -fields is-aes-encryption-enabled
```

The `is-aes-encryption-enabled` field displays `true` if AES encryption is enabled and `false` if it is disabled.

### Examples

The following example enables the AES encryption types for the SMB server on SVM vs1:

```
cluster1::> vserver cifs security modify -vserver vs1 -is-aes-
-encryption-enabled true

cluster1::> vserver cifs security show -vserver vs1 -fields is-aes-
-encryption-enabled

vserver is-aes-encryption-enabled

vs1 true
```

The following example enables the AES encryption types for the SMB server on SVM vs2. The administrator is prompted to enter the administrative AD credentials for the OU containing the SMB server.

```
cluster1::> vserver cifs security modify -vserver vs2 -is-aes-
-encryption-enabled true

Info: In order to enable SMB AES encryption, the password for the CIFS
server
machine account must be reset. Enter the username and password for the
SMB domain "EXAMPLE.COM".

Enter your user ID: administrator

Enter your password:

cluster1::> vserver cifs security show -vserver vs2 -fields is-aes-
-encryption-enabled

vserver is-aes-encryption-enabled

vs2 true
```

## Use SMB signing to enhance network security

### Use SMB signing to enhance network security overview

SMB signing helps to ensure that network traffic between the SMB server and the client is not compromised; it does this by preventing replay attacks. By default, ONTAP supports SMB signing when requested by the client. Optionally, the storage administrator can configure the SMB server to require SMB signing.

## How SMB signing policies affect communication with a CIFS server

In addition to the CIFS server SMB signing security settings, two SMB signing policies on Windows clients control the digital signing of communications between clients and the CIFS server. You can configure the setting that meets your business requirements.

Client SMB policies are controlled through Windows local security policy settings, which are configured by using the Microsoft Management Console (MMC) or Active Directory GPOs. For more information about client SMB signing and security issues, see the Microsoft Windows documentation.

Here are descriptions of the two SMB signing policies on Microsoft clients:

- Microsoft network client: Digitally sign communications (if server agrees)

This setting controls whether the client's SMB signing capability is enabled. It is enabled by default. When this setting is disabled on the client, the client communications with the CIFS server depends on the SMB signing setting on the CIFS server.

- Microsoft network client: Digitally sign communications (always)

This setting controls whether the client requires SMB signing to communicate with a server. It is disabled by default. When this setting is disabled on the client, SMB signing behavior is based on the policy setting for Microsoft network client: Digitally sign communications (if server agrees) and the setting on the CIFS server.

If your environment includes Windows clients configured to require SMB signing, you must enable SMB signing on the CIFS server. If you do not, the CIFS server cannot serve data to these systems.

The effective results of client and CIFS server SMB signing settings depends on whether the SMB sessions uses SMB 1.0 or SMB 2.x and later.

The following table summarizes the effective SMB signing behavior if the session uses SMB 1.0:

| Client                            | ONTAP—signing not required | ONTAP—signing required |
|-----------------------------------|----------------------------|------------------------|
| Signing disabled and not required | Not signed                 | Signed                 |
| Signing enabled and not required  | Not signed                 | Signed                 |
| Signing disabled and required     | Signed                     | Signed                 |
| Signing enabled and required      | Signed                     | Signed                 |

Older Windows SMB 1 clients and some non-Windows SMB 1 clients might fail to connect if signing is disabled on the client but required on the CIFS server.

The following table summarizes the effective SMB signing behavior if the session uses SMB 2.x or SMB 3.0:

For SMB 2.x and SMB 3.0 clients, SMB signing is always enabled. It cannot be disabled.

| Client               | ONTAP—signing not required | ONTAP—signing required |
|----------------------|----------------------------|------------------------|
| Signing not required | Not signed                 | Signed                 |
| Signing required     | Signed                     | Signed                 |

The following table summarizes the default Microsoft client and server SMB signing behavior:

| Protocol | Hash algorithm | Can enable/disable | Can require/not require | Client default         | Server default          | DC default |
|----------|----------------|--------------------|-------------------------|------------------------|-------------------------|------------|
| SMB 1.0  | MD5            | Yes                | Yes                     | Enabled (not required) | Disabled (not required) | Required   |
| SMB 2.x  | HMAC SHA-256   | No                 | Yes                     | Not required           | Not required            | Required   |
| SMB 3.0  | AES-CMAC.      | No                 | Yes                     | Not required           | Not required            | Required   |

 Microsoft no longer recommends using Digitally sign communications (if client agrees) or Digitally sign communications (if server agrees) Group Policy settings. Microsoft also no longer recommends using the EnableSecuritySignature registry settings. These options only affect the SMB 1 behavior and can be replaced by the Digitally sign communications (always) Group Policy setting or the RequireSecuritySignature registry setting. You can also get more information from the Microsoft Blog.<http://blogs.technet.com/b/josebda/archive/2010/12/01/the-basics-of-smb-signing-covering-both-smb1-and-smb2.aspx>[The Basics of SMB Signing (covering both SMB1 and SMB2)]

## Performance impact of SMB signing

When SMB sessions use SMB signing, all SMB communications to and from Windows clients experience a performance impact, which affects both the clients and the server (that is, the nodes on the cluster running the SVM containing the SMB server).

The performance impact shows as increased CPU usage on both the clients and the server, although the amount of network traffic does not change.

The extent of the performance impact depends on the version of ONTAP 9 you are running. Beginning with ONTAP 9.7, a new encryption off-load algorithm can enable better performance in signed SMB traffic. SMB signing offload is enabled by default when SMB signing is enabled.

Enhanced SMB signing performance requires AES-NI offload capability. See the Hardware Universe (HWU) to verify that AES-NI offload is supported for your platform.

Further performance improvements are also possible if you are able to use SMB version 3.11 (supported with Windows 10 and Windows Server 2016), which supports the much faster GCM algorithm.

Depending on your network, ONTAP 9 version, SMB version, and SVM implementation, the performance

impact of SMB signing can vary widely; you can verify it only through testing in your network environment.

Most Windows clients negotiate SMB signing by default if it is enabled on the server. If you require SMB protection for some of your Windows clients, and if SMB signing is causing performance issues, you can disable SMB signing on any of your Windows clients that do not require protection against replay attacks. For information about disabling SMB signing on Windows clients, see the Microsoft Windows documentation.

### Recommendations for configuring SMB signing

You can configure SMB signing behavior between SMB clients and the CIFS server to meet your security requirements. The settings you choose when configuring SMB signing on your CIFS server are dependent on what your security requirements are.

You can configure SMB signing on either the client or the CIFS server. Consider the following recommendations when configuring SMB signing:

| If...                                                                                    | Recommendation...                                                                                                    |
|------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------|
| You want to increase the security of the communication between the client and the server | Make SMB signing required at the client by enabling the Require Option (Sign always) security setting on the client. |
| You want all SMB traffic to a certain storage virtual machine (SVM) signed               | Make SMB signing required on the CIFS server by configuring the security settings to require SMB signing.            |

See Microsoft documentation for more information on configuring Windows client security settings.

### Guidelines for SMB signing when multiple data LIFs are configured

If you enable or disable required SMB signing on the SMB server, you should be aware of the guidelines for multiple data LIFs configurations for an SVM.

When you configure a SMB server, there might be multiple data LIFs configured. If so, the DNS server contains multiple A record entries for the CIFS server, all using the same SMB server host name, but each with a unique IP address. For example, a SMB server that has two data LIFs configured might have the following DNS A record entries:

```
10.1.1.128 A VS1.IEPUB.LOCAL VS1
10.1.1.129 A VS1.IEPUB.LOCAL VS1
```

The normal behavior is that upon changing the required SMB signing setting, only new connections from clients are affected by the change in the SMB signing setting. However, there is an exception to this behavior. There is a case where a client has an existing connection to a share, and the client creates a new connection to the same share after the setting is changed, while maintaining the original connection. In this case, both the new and the existing SMB connection adopt the new SMB signing requirements.

Consider the following example:

1. Client1 connects to a share without required SMB signing using the path O:\.

2. The storage administrator modifies the SMB server configuration to require SMB signing.
3. Client1 connects to the same share with required SMB signing using the path `s:\` (while maintaining the connection using the path `o:\`).
4. The result is that SMB signing is used when accessing data over both the `o:\` and `s:\` drives.

### **Enable or disable required SMB signing for incoming SMB traffic**

You can enforce the requirement for clients to sign SMB messages by enabling required SMB signing. If enabled, ONTAP accepts SMB messages only if they have valid signatures. If you want to permit SMB signing, but not require it, you can disable required SMB signing.

#### **About this task**

By default, required SMB signing is disabled. You can enable or disable required SMB signing at any time.

SMB signing is not disabled by default under the following circumstances:

- 1. Required SMB signing is enabled, and the cluster is reverted to a version of ONTAP that does not support SMB signing.
- 2. The cluster is subsequently upgraded to a version of ONTAP that supports SMB signing.

 Under these circumstances, the SMB signing configuration that was originally configured on a supported version of ONTAP is retained through reversion and subsequent upgrade.

When you set up a storage virtual machine (SVM) disaster recovery relationship, the value that you select for the `-identity-preserve` option of the `snapmirror create` command determines the configuration details that are replicated in the destination SVM.

If you set the `-identity-preserve` option to `true` (ID-preserve), the SMB signing security setting is replicated to the destination.

If you set the `-identity-preserve` option to `false` (non-ID-preserve), the SMB signing security setting is not replicated to the destination. In this case, the CIFS server security settings on the destination are set to the default values. If you have enabled required SMB signing on the source SVM, you must manually enable required SMB signing on the destination SVM.

#### **Steps**

1. Perform one of the following actions:

| <b>If you want required SMB signing to be...</b> | <b>Enter the command...</b>                                                                |
|--------------------------------------------------|--------------------------------------------------------------------------------------------|
| Enabled                                          | <code>vserver cifs security modify -vserver vserver_name -is-signing-required true</code>  |
| Disabled                                         | <code>vserver cifs security modify -vserver vserver_name -is-signing-required false</code> |

2. Verify that required SMB signing is enabled or disabled by determining whether the value in the Is Signing Required field in the output of the following command is set to the desired value: vserver cifs security show -vserver *vserver\_name* -fields is-signing-required

### Example

The following example enables required SMB signing for SVM vs1:

```
cluster1::> vserver cifs security modify -vserver vs1 -is-signing-required true

cluster1::> vserver cifs security show -vserver vs1 -fields is-signing-required
vserver is-signing-required

vs1 true
```

### Determine whether SMB sessions are signed

You can display information about connected SMB sessions on the CIFS server. You can use this information to determine whether SMB sessions are signed. This can be helpful in determining whether SMB client sessions are connecting with the desired security settings.

#### Steps

1. Perform one of the following actions:

| If you want display information about...                           | Enter the command...                                                                 |
|--------------------------------------------------------------------|--------------------------------------------------------------------------------------|
| All signed sessions on a specified storage virtual machine (SVM)   | vserver cifs session show -vserver <i>vserver_name</i> -is-session-signed true       |
| Details for a signed session with a specific session ID on the SVM | vserver cifs session show -vserver <i>vserver_name</i> -session-id integer -instance |

### Examples

The following command displays session information about signed sessions on SVM vs1. The default summary output does not display the "Is Session Signed" output field:

```

cluster1::> vserver cifs session show -vserver vs1 -is-session-signed true
Node: node1
Vserver: vs1
Connection Session
ID ID Workstation Windows User Open Idle
----- ----- -----
3151272279 1 10.1.1.1 DOMAIN\joe 2 23s

```

The following command displays detailed session information, including whether the session is signed, on an SMB session with a session ID of 2:

```

cluster1::> vserver cifs session show -vserver vs1 -session-id 2 -instance
 Node: node1
 Vserver: vs1
 Session ID: 2
 Connection ID: 3151274158
Incoming Data LIF IP Address: 10.2.1.1
 Workstation: 10.1.1.2
Authentication Mechanism: Kerberos
 Windows User: DOMAIN\joe
 UNIX User: pcuser
 Open Shares: 1
 Open Files: 1
 Open Other: 0
 Connected Time: 10m 43s
 Idle Time: 1m 19s
 Protocol Version: SMB3
Continuously Available: No
 Is Session Signed: true
User Authenticated as: domain-user
 NetBIOS Name: CIFS_ALIAS1
SMB Encryption Status: Unencrypted

```

## Related information

[Monitoring SMB signed session statistics](#)

## Monitor SMB signed session statistics

You can monitor SMB sessions statistics and determine which established sessions are signed and which are not.

## About this task

The `statistics` command at the advanced privilege level provides the `signed_sessions` counter that you can use to monitor the number of signed SMB sessions. The `signed_sessions` counter is available with the following statistics objects:

- `cifs` enables you to monitor SMB signing for all SMB sessions.
- `smb1` enables you to monitor SMB signing for SMB 1.0 sessions.
- `smb2` enables you to monitor SMB signing for SMB 2.x and SMB 3.0 sessions.

SMB 3.0 statistics are included in the output for the `smb2` object.

If you want to compare the number of signed session to the total number of sessions, you can compare output for the `signed_sessions` counter with the output for the `established_sessions` counter.

You must start a statistics sample collection before you can view the resultant data. You can view data from the sample if you do not stop data collection. Stopping data collection gives you a fixed sample. Not stopping data collection gives you the ability to get updated data that you can use to compare against previous queries. The comparison can help you identify trends.

## Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Start a data collection:

```
statistics start -object {cifs|smb1|smb2} -instance instance -sample-id
sample_ID [-node node_name]
```

If you do not specify the `-sample-id` parameter, the command generates a sample identifier for you and defines this sample as the default sample for the CLI session. The value for `-sample-id` is a text string. If you run this command during the same CLI session and do not specify the `-sample-id` parameter, the command overwrites the previous default sample.

You can optionally specify the node on which you want to collect statistics. If you do not specify the node, the sample collects statistics for all nodes in the cluster.

3. Use the `statistics stop` command to stop collecting data for the sample.

4. View SMB signing statistics:

| If you want to view information for...   | Enter...                                                                                                         |
|------------------------------------------|------------------------------------------------------------------------------------------------------------------|
| Signed sessions                          | <code>show -sample-id sample_ID -counter signed_sessions node_name [-node node_name]</code>                      |
| Signed sessions and established sessions | <code>show -sample-id sample_ID -counter signed_sessions established_sessions node_name [-node node_name]</code> |

If you want to display information for only a single node, specify the optional `-node` parameter.

5. Return to the admin privilege level:

```
set -privilege admin
```

## Examples

The following example shows how you can monitor SMB 2.x and SMB 3.0 signing statistics on storage virtual machine (SVM) vs1.

The following command moves to the advanced privilege level:

```
cluster1::> set -privilege advanced
```

Warning: These advanced commands are potentially dangerous; use them only when directed to do so by support personnel.

Do you want to continue? {y|n}: y

The following command starts data collection for a new sample:

```
cluster1::*> statistics start -object smb2 -sample-id smbsigning_sample
-vserver vs1
```

```
Statistics collection is being started for Sample-id: smbsigning_sample
```

The following command stops the data collection for the sample:

```
cluster1::*> statistics stop -sample-id smbsigning_sample
Statistics collection is being stopped for Sample-id: smbsigning_sample
```

The following command shows signed SMB sessions and established SMB sessions by node from the sample:

```
cluster1::*> statistics show -sample-id smbsigning_sample -counter signed_sessions|established_sessions|node_name
```

```
Object: smb2
Instance: vs1
Start-time: 2/6/2013 01:00:00
End-time: 2/6/2013 01:03:04
Cluster: cluster1
```

| Counter              | Value |
|----------------------|-------|
| <hr/>                |       |
| established_sessions | 0     |
| node_name            | node1 |
| signed_sessions      | 0     |
| established_sessions | 1     |
| node_name            | node2 |
| signed_sessions      | 1     |
| established_sessions | 0     |
| node_name            | node3 |
| signed_sessions      | 0     |
| established_sessions | 0     |
| node_name            | node4 |
| signed_sessions      | 0     |

The following command shows signed SMB sessions for node2 from the sample:

```
cluster1::*> statistics show -sample-id smbsigning_sample -counter signed_sessions|node_name -node node2
```

```
Object: smb2
Instance: vs1
Start-time: 2/6/2013 01:00:00
End-time: 2/6/2013 01:22:43
Cluster: cluster1
```

| Counter         | Value |
|-----------------|-------|
| <hr/>           |       |
| node_name       | node2 |
| signed_sessions | 1     |

The following command moves back to the admin privilege level:

```
cluster1::*> set -privilege admin
```

**Configure required SMB encryption on SMB servers for data transfers over SMB**

### SMB encryption overview

SMB encryption for data transfers over SMB is a security enhancement that you can enable or disable on SMB servers. You can also configure the desired SMB encryption setting on a share-by-share basis through a share property setting.

By default, when you create a SMB server on the storage virtual machine (SVM), SMB encryption is disabled. You must enable it to take advantage of the enhanced security provided by SMB encryption.

To create an encrypted SMB session, the SMB client must support SMB encryption. Windows clients beginning with Windows Server 2012 and Windows 8 support SMB encryption.

SMB encryption on the SVM is controlled through two settings:

- A SMB server security option that enables the functionality on the SVM
- A SMB share property that configures the SMB encryption setting on a share-by-share basis

You can decide whether to require encryption for access to all data on the SVM or to require SMB encryption to access data only in selected shares. SVM-level settings supersede share-level settings.

The effective SMB encryption configuration depends on the combination of the two settings and is described in the following table:

| SMB server SMB encryption enabled | Share encrypt data setting enabled | Server-side encryption behavior                                                                                                                                                     |
|-----------------------------------|------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| True                              | False                              | Server-level encryption is enabled for all of the shares in the SVM. With this configuration, encryption happens for the entire SMB session.                                        |
| True                              | True                               | Server-level encryption is enabled for all of the shares in the SVM irrespective of share-level encryption. With this configuration, encryption happens for the entire SMB session. |
| False                             | True                               | Share-level encryption is enabled for the specific shares. With this configuration, encryption happens from the tree connect.                                                       |

| SMB server SMB encryption enabled | Share encrypt data setting enabled | Server-side encryption behavior |
|-----------------------------------|------------------------------------|---------------------------------|
| False                             | False                              | No encryption is enabled.       |

SMB clients that do not support encryption cannot connect to a SMB server or share that requires encryption.

### Performance impact of SMB encryption

When SMB sessions use SMB encryption, all SMB communications to and from Windows clients experience a performance impact, which affects both the clients and the server (that is, the nodes on the cluster running the SVM that contains the SMB server).

The performance impact shows as increased CPU usage on both the clients and the server, although the amount of network traffic does not change.

The extent of the performance impact depends on the version of ONTAP 9 you are running. Beginning with ONTAP 9.7, a new encryption off-load algorithm can enable better performance in encrypted SMB traffic. SMB encryption offload is enabled by default when SMB encryption is enabled.

Enhanced SMB encryption performance requires AES-NI offload capability. See the Hardware Universe (HWU) to verify that AES-NI offload is supported for your platform.

Further performance improvements are also possible if you are able to use SMB version 3.11 (supported with Windows 10 and Windows Server 2016), which supports the much faster GCM algorithm.

Depending on your network, ONTAP 9 version, SMB version, and SVM implementation, the performance impact of SMB encryption can vary widely; you can verify it only through testing in your network environment.

SMB encryption is disabled by default on the SMB server. You should enable SMB encryption only on those SMB shares or SMB servers that require encryption. With SMB encryption, ONTAP performs additional processing of decrypting the requests and encrypting the responses for every request. SMB encryption should therefore be enabled only when necessary.

### Enable or disable required SMB encryption for incoming SMB traffic

If you want to require SMB encryption for incoming SMB traffic you can enable it on the CIFS server or at the share level. By default, SMB encryption is not required.

#### About this task

You can enable SMB encryption on the CIFS server, which applies to all shares on the CIFS server. If you do not want required SMB encryption for all shares on the CIFS server or if you want to enable required SMB encryption for incoming SMB traffic on a share-by-share basis, you can disable required SMB encryption on the CIFS server.

When you set up a storage virtual machine (SVM) disaster recovery relationship, the value you select for the `-identity-preserve` option of the `snapmirror create` command determines the configuration details that are replicated in the destination SVM.

If you set the `-identity-preserve` option to `true` (ID-preserve), the SMB encryption security setting is replicated to the destination.

If you set the `-identity-preserve` option to `false` (non-ID-preserve), the SMB encryption security setting is not replicated to the destination. In this case, the CIFS server security settings on the destination are set to the default values. If you have enabled SMB encryption on the source SVM, you must manually enable CIFS server SMB encryption on the destination.

## Steps

1. Perform one of the following actions:

| If you want required SMB encryption for incoming SMB traffic on the CIFS server to be... | Enter the command...                                                                              |
|------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------|
| Enabled                                                                                  | <code>vserver cifs security modify -vserver vserver_name -is-smb-encryption-required true</code>  |
| Disabled                                                                                 | <code>vserver cifs security modify -vserver vserver_name -is-smb-encryption-required false</code> |

2. Verify that required SMB encryption on the CIFS server is enabled or disabled as desired: `vserver cifs security show -vserver vserver_name -fields is-smb-encryption-required`

The `is-smb-encryption-required` field displays `true` if required SMB encryption is enabled on the CIFS server and `false` if it is disabled.

## Example

The following example enables required SMB encryption for incoming SMB traffic for the CIFS server on SVM `vs1`:

```
cluster1::> vserver cifs security modify -vserver vs1 -is-smb-encryption-required true

cluster1::> vserver cifs security show -vserver vs1 -fields is-smb-encryption-required
vserver is-smb-encryption-required

vs1 true
```

## Determine whether clients are connected using encrypted SMB sessions

You can display information about connected SMB sessions to determine whether clients are using encrypted SMB connections. This can be helpful in determining whether SMB client sessions are connecting with the desired security settings.

### About this task

SMB clients sessions can have one of three encryption levels:

- unencrypted

The SMB session is not encrypted. Neither storage virtual machine (SVM)-level or share-level encryption is configured.

- partially-encrypted

Encryption is initiated when the tree-connect occurs. Share-level encryption is configured. SVM-level encryption is not enabled.

- encrypted

The SMB session is fully encrypted. SVM-level encryption is enabled. Share level encryption might or might not be enabled. The SVM-level encryption setting supersedes the share-level encryption setting.

## Steps

1. Perform one of the following actions:

| If you want display information about...                                     | Enter the command...                                                                                                      |
|------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------|
| Sessions with a specified encryption setting for sessions on a specified SVM | <code>vserver cifs session show -vserver <i>vserver_name</i> {unencrypted partially-encrypted encrypted} -instance</code> |
| The encryption setting for a specific session ID on a specified SVM          | <code>vserver cifs session show -vserver <i>vserver_name</i> -session-id <i>integer</i> -instance</code>                  |

## Examples

The following command displays detailed session information, including the encryption setting, on an SMB session with a session ID of 2:

```

cluster1::> vserver cifs session show -vserver vs1 -session-id 2 -instance
 Node: node1
 Vserver: vs1
 Session ID: 2
 Connection ID: 3151274158
Incoming Data LIF IP Address: 10.2.1.1
 Workstation: 10.1.1.2
Authentication Mechanism: Kerberos
 Windows User: DOMAIN\joe
 UNIX User: pcuser
 Open Shares: 1
 Open Files: 1
 Open Other: 0
Connected Time: 10m 43s
 Idle Time: 1m 19s
Protocol Version: SMB3
Continuously Available: No
 Is Session Signed: true
User Authenticated as: domain-user
 NetBIOS Name: CIFS_ALIAS1
SMB Encryption Status: Unencrypted

```

## Monitor SMB encryption statistics

You can monitor SMB encryption statistics and determine which established sessions and share connections are encrypted and which are not.

### About this task

The `statistics` command at the advanced privilege level provides the following counters, which you can use to monitor the number of encrypted SMB sessions and share connections:

| Counter name                               | Descriptions                                                                              |
|--------------------------------------------|-------------------------------------------------------------------------------------------|
| <code>encrypted_sessions</code>            | Gives the number of encrypted SMB 3.0 sessions                                            |
| <code>encrypted_share_connections</code>   | Gives the number of encrypted shares on which a tree connect has happened                 |
| <code>rejected_unencrypted_sessions</code> | Gives the number of session setups rejected due to a lack of client encryption capability |
| <code>rejected_unencrypted_shares</code>   | Gives the number of share mappings rejected due to a lack of client encryption capability |

These counters are available with the following statistics objects:

- `cifs` enables you to monitor SMB encryption for all SMB 3.0 sessions.

SMB 3.0 statistics are included in the output for the `cifs` object. If you want to compare the number of encrypted sessions to the total number of sessions, you can compare output for the `encrypted_sessions` counter with the output for the `established_sessions` counter.

If you want to compare the number of encrypted share connections to the total number of share connections, you can compare output for the `encrypted_share_connections` counter with the output for the `connected_shares` counter.

- `rejected_unencrypted_sessions` provides the number of times an attempt has been made to establish an SMB session that requires encryption from a client that does not support SMB encryption.
- `rejected_unencrypted_shares` provides the number of times an attempt has been made to connect to an SMB share that requires encryption from a client that does not support SMB encryption.

You must start a statistics sample collection before you can view the resultant data. You can view data from the sample if you do not stop the data collection. Stopping data collection gives you a fixed sample. Not stopping data collection gives you the ability to get updated data that you can use to compare against previous queries. The comparison can help you identify trends.

## Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Start a data collection:

```
statistics start -object {cifs|smb1|smb2} -instance instance -sample-id sample_ID [-node node_name]
```

If you do not specify the `-sample-id` parameter, the command generates a sample identifier for you and defines this sample as the default sample for the CLI session. The value for `-sample-id` is a text string. If you run this command during the same CLI session and do not specify the `-sample-id` parameter, the command overwrites the previous default sample.

You can optionally specify the node on which you want to collect statistics. If you do not specify the node, the sample collects statistics for all nodes in the cluster.

3. Use the `statistics stop` command to stop collecting data for the sample.

4. View SMB encryption statistics:

| If you want to view information for...      | Enter...                                                                                                                                       |
|---------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------|
| Encrypted sessions                          | <code>show -sample-id <i>sample_ID</i> -counter encrypted_sessions -node <i>node_name</i> [-node <i>node_name</i>]</code>                      |
| Encrypted sessions and established sessions | <code>show -sample-id <i>sample_ID</i> -counter encrypted_sessions established_sessions -node <i>node_name</i> [-node <i>node_name</i>]</code> |

| If you want to view information for...           | Enter...                                                                                                                           |
|--------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------|
| Encrypted share connections                      | show -sample-id <i>sample_ID</i> -counter encrypted_share_connections  <i>node_name</i> [-node <i>node_name</i> ]                  |
| Encrypted share connections and connected shares | show -sample-id <i>sample_ID</i> -counter encrypted_share_connections connected_shares  <i>node_name</i> [-node <i>node_name</i> ] |
| Rejected unencrypted sessions                    | show -sample-id <i>sample_ID</i> -counter rejected_unencrypted_sessions  <i>node_name</i> [-node <i>node_name</i> ]                |
| Rejected unencrypted share connections           | show -sample-id <i>sample_ID</i> -counter rejected_unencrypted_share  <i>node_name</i> [-node <i>node_name</i> ]                   |

If you want to display information only for a single node, specify the optional –node parameter.

5. Return to the admin privilege level:

```
set -privilege admin
```

## Examples

The following example shows how you can monitor SMB 3.0 encryption statistics on storage virtual machine (SVM) vs1.

The following command moves to the advanced privilege level:

```
cluster1::> set -privilege advanced
```

Warning: These advanced commands are potentially dangerous; use them only when directed to do so by support personnel.

Do you want to continue? {y|n}: y

The following command starts data collection for a new sample:

```
cluster1::*> statistics start -object cifs -sample-id
smbencryption_sample -vserver vs1
Statistics collection is being started for Sample-id:
smbencryption_sample
```

The following command stops data collection for that sample:

```
cluster1::*> statistics stop -sample-id smbencryption_sample
Statistics collection is being stopped for Sample-id:
smbencryption_sample
```

The following command shows encrypted SMB sessions and established SMB sessions by the node from the sample:

```

cluster2::*> statistics show -object cifs -counter
established_sessions|encrypted_sessions|node_name -node node_name

Object: cifs
Instance: [proto_ctx:003]
Start-time: 4/12/2016 11:17:45
End-time: 4/12/2016 11:21:45
Scope: vsim2

 Counter Value
----- -----
established_sessions 1
encrypted_sessions 1

2 entries were displayed

```

The following command shows the number of rejected unencrypted SMB sessions by the node from the sample:

```

clus-2::*> statistics show -object cifs -counter
rejected_unencrypted_sessions -node node_name

Object: cifs
Instance: [proto_ctx:003]
Start-time: 4/12/2016 11:17:45
End-time: 4/12/2016 11:21:51
Scope: vsim2

 Counter Value
----- -----
rejected_unencrypted_sessions 1

1 entry was displayed.

```

The following command shows the number of connected SMB shares and encrypted SMB shares by the node from the sample:

```

clus-2::*> statistics show -object cifs -counter
connected_shares|encrypted_share_connections|node_name -node node_name

Object: cifs
Instance: [proto_ctx:003]
Start-time: 4/12/2016 10:41:38
End-time: 4/12/2016 10:41:43
Scope: vsim2

 Counter Value
----- -----
connected_shares 2
encrypted_share_connections 1

2 entries were displayed.

```

The following command shows the number of rejected unencrypted SMB share connections by the node from the sample:

```

clus-2::*> statistics show -object cifs -counter
rejected_unencrypted_shares -node node_name

Object: cifs
Instance: [proto_ctx:003]
Start-time: 4/12/2016 10:41:38
End-time: 4/12/2016 10:42:06
Scope: vsim2

 Counter Value
----- -----
rejected_unencrypted_shares 1

1 entry was displayed.

```

## Related information

[Determining which statistics objects and counters are available](#)

[Performance monitoring and management overview](#)

[Secure LDAP session communication](#)

**LDAP signing and sealing concepts**

Beginning with ONTAP 9, you can configure signing and sealing to enable LDAP session security on queries to an Active Directory (AD) server. You must configure the CIFS

server security settings on the storage virtual machine (SVM) to correspond to those on the LDAP server.

Siging confirms the integrity of the LDAP payload data using secret key technology. Sealing encrypts the LDAP payload data to avoid transmitting sensitive information in clear text. An *LDAP Security Level* option indicates whether the LDAP traffic needs to be signed, signed and sealed, or neither. The default is none.

LDAP signing and sealing on CIFS traffic is enabled on the SVM with the `-session-security-for-ad-ldap` option to the `vserver cifs security modify` command.

### Enable LDAP signing and sealing on the CIFS server

Before your CIFS server can use signing and sealing for secure communication with an Active Directory LDAP server, you must modify the CIFS server security settings to enable LDAP signing and sealing.

#### Before you begin

You must consult with your AD server administrator to determine the appropriate security configuration values.

#### Steps

1. Configure the CIFS server security setting that enables signed and sealed traffic with Active Directory LDAP servers: `vserver cifs security modify -vserver vserver_name -session-security-for-ad-ldap {none|sign|seal}`

You can enable signing (sign, data integrity), signing and sealing (seal, data integrity and encryption), or neither (none, no signing or sealing). The default value is none.

2. Verify that the LDAP signing and sealing security setting is set correctly: `vserver cifs security show -vserver vserver_name`

If the SVM uses the same LDAP server for querying name-mapping or other UNIX information, such as users, groups, and netgroups, then you must enable the corresponding setting with the `-session-security` option of the `vserver services name-service ldap client modify` command.

### Configure LDAP over TLS

#### Export a copy of the self-signed root CA certificate

To use LDAP over SSL/TLS for securing Active Directory communication, you must first export a copy of the Active Directory Certificate Service's self-signed root CA certificate to a certificate file and convert it to an ASCII text file. This text file is used by ONTAP to install the certificate on the storage virtual machine (SVM).

#### Before you begin

The Active Directory Certificate Service must already be installed and configured for the domain to which the CIFS server belongs. You can find information about installing and configuring Active Director Certificate Services by consulting the Microsoft TechNet Library.

## Step

1. Obtain a root CA certificate of the domain controller that is in the .pem text format.

[Microsoft TechNet Library: technet.microsoft.com](http://Microsoft TechNet Library: technet.microsoft.com)

## After you finish

Install the certificate on the SVM.

## Related information

[Microsoft TechNet Library](http://Microsoft TechNet Library)

## Install the self-signed root CA certificate on the SVM

If LDAP authentication with TLS is required when binding to LDAP servers, you must first install the self-signed root CA certificate on the SVM.

### About this task

When LDAP over TLS is enabled, the ONTAP LDAP client on the SVM does not support revoked certificates in ONTAP 9.0 and 9.1.

Beginning with ONTAP 9.2, all applications within ONTAP that use TLS communications can check digital certificate status using Online Certificate Status Protocol (OCSP). If OCSP is enabled for LDAP over TLS, revoked certificates are rejected and the connection fails.

### Steps

1. Install the self-signed root CA certificate:

a. Begin the certificate installation: `security certificate install -vserver vserver_name -type server-ca`

The console output displays the following message: Please enter Certificate: Press <Enter> when done

b. Open the certificate .pem file with a text editor, copy the certificate, including the lines beginning with -----BEGIN CERTIFICATE----- and ending with -----END CERTIFICATE-----, and then paste the certificate after the command prompt.

- c. Verify that the certificate is displayed correctly.
- d. Complete the installation by pressing Enter.

2. Verify that the certificate is installed: `security certificate show -vserver vserver_name`

## Enable LDAP over TLS on the server

Before your SMB server can use TLS for secure communication with an Active Directory LDAP server, you must modify the SMB server security settings to enable LDAP over TLS.

Beginning with ONTAP 9.10.1, LDAP channel binding is supported by default for both Active Directory (AD) and name services LDAP connections. ONTAP will try channel binding with LDAP connections only if Start-TLS or LDAPS is enabled along with session security set to either sign or seal. To disable or reenable LDAP channel binding with AD servers, use the `-try-channel-binding-for-ad-ldap` parameter with the

```
vserver cifs security modify command.
```

To learn more, see:

- [LDAP overview](#)
- [2020 LDAP channel binding and LDAP signing requirements for Windows](#).

## Steps

1. Configure the SMB server security setting that allows secure LDAP communication with Active Directory LDAP servers: `vserver cifs security modify -vserver vserver_name -use-start-tls -for-ad-ldap true`
2. Verify that the LDAP over TLS security setting is set to true: `vserver cifs security show -vserver vserver_name`

If the SVM uses the same LDAP server for querying name-mapping or other UNIX information (such as users, groups, and netgroups), then you must also modify the `-use-start-tls` option by using the `vserver services name-service ldap client modify` command.

## Configure SMB Multichannel for performance and redundancy

Beginning with ONTAP 9.4, you can configure SMB Multichannel to provide multiple connections between ONTAP and clients in a single SMB session. Doing so improves throughput and fault tolerance.

### Before you begin

You can use SMB Multichannel functionality only when clients negotiate at SMB 3.0 or later versions. SMB 3.0 and later is enabled on the ONTAP SMB server by default.

### About this task

SMB clients automatically detect and use multiple network connections if a proper configuration is identified on the ONTAP cluster.

The number of simultaneous connections in an SMB session depends on the NICs you have deployed:

- **1G NICs on client and ONTAP cluster**

The client establishes one connection per NIC and binds the session to all connections.

- **10G and larger capacity NICs on client and ONTAP cluster**

The client establishes up to four connections per NIC and binds the session to all connections. The client can establish connections on multiple 10G and larger capacity NICs.

You can also modify the following parameters (advanced privilege):

- **-max-connections-per-session**

The maximum number of connections allowed per Multichannel session. The default is 32 connections.

If you want to enable more connections than the default, you must make comparable adjustments to the

client configuration, which also has a default of 32 connections.

- **-max-lifs-per-session**

The maximum number of network interfaces advertised per Multichannel session. The default is 256 network interfaces.

## Steps

1. Set the privilege level to advanced: `set -privilege advanced`
2. Enable SMB Multichannel on the SMB server: `vserver cifs options modify -vserver vserver_name -is-multichannel-enabled true`
3. Verify that ONTAP is reporting SMB Multichannel sessions: `vserver cifs session show options`
4. Return to the admin privilege level: `set -privilege admin`

## Example

The following example displays information about all SMB sessions, showing multiple connections for a single session:

```
cluster1::> vserver cifs session show
Node: node1
Vserver: vs1
Connection Session Open
Idle
IDs ID Workstation Windows User Files
Time

138683,
138684,
138685 1 10.1.1.1 DOMAIN\ 0
4s Administrator
```

The following example displays detailed information about an SMB session with session-id 1:

```
cluster1::> vserver cifs session show -session-id 1 -instance

Vserver: vs1
 Node: node1
 Session ID: 1
 Connection IDs: 138683,138684,138685
 Connection Count: 3
 Incoming Data LIF IP Address: 192.1.1.1
 Workstation IP Address: 10.1.1.1
 Authentication Mechanism: NTLMv1
 User Authenticated as: domain-user
 Windows User: DOMAIN\administrator
 UNIX User: root
 Open Shares: 2
 Open Files: 5
 Open Other: 0
 Connected Time: 5s
 Idle Time: 5s
 Protocol Version: SMB3
 Continuously Available: No
 Is Session Signed: false
 NetBIOS Name: -
```

## Configure default Windows user to UNIX user mappings on the SMB server

### Configure the default UNIX user

You can configure the default UNIX user to use if all other mapping attempts fail for a user, or if you do not want to map individual users between UNIX and Windows. Alternatively, if you want authentication of non-mapped users to fail, you should not configure the default UNIX user.

### About this task

By default, the name of the default UNIX user is “pcuser”, which means that, by default, user mapping to the default UNIX user is enabled. You can specify another name to use as the default UNIX user. The name that you specify must exist in the name service databases configured for the storage virtual machine (SVM). If this option is set to a null string, no one can access the CIFS server as a UNIX default user. That is, each user must have an account in the password database before they can access the CIFS server.

For a user to connect to the CIFS server using the default UNIX user account, the user must meet the following prerequisites:

- The user is authenticated.
- The user is in the CIFS server’s local Windows user database, in the CIFS server’s home domain, or in a trusted domain (if multidomain name mapping searches is enabled on the CIFS server).
- The user name is not explicitly mapped to a null string.

## Steps

1. Configure the default UNIX user:

| If you want to ...                                | Enter ...                                                        |
|---------------------------------------------------|------------------------------------------------------------------|
| Use the default UNIX user “pcuser”                | vserver cifs options modify -default -unix-user pcuser           |
| Use another UNIX user account as the default user | vserver cifs options modify -default -unix-user <i>user_name</i> |
| Disable the default UNIX user                     | vserver cifs options modify -default -unix-user ""               |

```
vserver cifs options modify -default-unix-user pcuser
```

2. Verify that the default UNIX user is configured correctly: `vserver cifs options show -vserver vserver_name`

In the following example, both the default UNIX user and the guest UNIX user on SVM vs1 are configured to use UNIX user “pcuser”:

```
vserver cifs options show -vserver vs1
```

```
Vserver: vs1

Client Session Timeout : 900
Default Unix Group : -
Default Unix User : pcuser
Guest Unix User : pcuser
Read Grants Exec : disabled
Read Only Delete : disabled
WINS Servers : -
```

## Configure the guest UNIX user

Configuring the guest UNIX user option means that users who log in from untrusted domains are mapped to the guest UNIX user and can connect to the CIFS server. Alternatively, if you want authentication of users from untrusted domains to fail, you should not configure the guest UNIX user. The default is to not allow users from untrusted domains to connect to the CIFS server (the guest UNIX account is not configured).

## About this task

You should keep the following in mind when configuring the guest UNIX account:

- If the CIFS server cannot authenticate the user against a domain controller for the home domain or a trusted domain or the local database and this option is enabled, the CIFS server considers the user as a

guest user and maps the user to the specified UNIX user.

- If this option is set to a null string, the guest UNIX user is disabled.
- You must create a UNIX user to use as the guest UNIX user in one of the storage virtual machine (SVM) name service databases.
- A user logged in as a guest user is automatically a member of the BUILTIN\guests group on the CIFS server.
- The 'homedirs-public' option applies only to authenticated users. A user logged in as a guest user does not have a home directory and cannot access other users' home directories.

## Steps

1. Perform one of the following actions:

| If you want to...             | Enter...                                                       |
|-------------------------------|----------------------------------------------------------------|
| Configure the guest UNIX user | vserver cifs options modify -guest -unix-user <i>unix_name</i> |
| Disable the guest UNIX user   | vserver cifs options modify -guest -unix-user ""               |

```
vserver cifs options modify -guest-unix-user pcuser
```

2. Verify that the guest UNIX user is configured correctly: `vserver cifs options show -vserver vserver_name`

In the following example, both the default UNIX user and the guest UNIX user on SVM vs1 are configured to use UNIX user "pcuser":

```
vserver cifs options show -vserver vs1
```

```
Vserver: vs1

Client Session Timeout : 900
Default Unix Group : -
Default Unix User : pcuser
Guest Unix User : pcuser
Read Grants Exec : disabled
Read Only Delete : disabled
WINS Servers : -
```

## Map the administrators group to root

If you have only CIFS clients in your environment and your storage virtual machine (SVM) was set up as a multiprotocol storage system, you must have at least one Windows account that has root privilege for accessing files on the SVM; otherwise, you cannot manage the SVM because you do not have sufficient user rights.

## About this task

If your storage system was set up as NTFS-only, however, the `/etc` directory has a file-level ACL that enables the administrators group to access the ONTAP configuration files.

## Steps

1. Set the privilege level to advanced: `set -privilege advanced`
2. Configure the CIFS server option that maps the administrators group to root as appropriate:

| If you want to...                                        | Then...                                                                                                                                                                                                                                                                                                                                                                                                                    |
|----------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Map the administrator group members to root              | <code>vserver cifs options modify -vserver vserver_name -is-admin-users-mapped-to-root-enabled true</code> All accounts in the administrators group are considered root, even if you do not have an <code>/etc/usermap.cfg</code> entry mapping the accounts to root. If you create a file using an account that belongs to the administrators group, the file is owned by root when you view the file from a UNIX client. |
| Disable mapping the administrators group members to root | <code>vserver cifs options modify -vserver vserver_name -is-admin-users-mapped-to-root-enabled false</code> Accounts in the administrators group no longer map to root. You can only explicitly map a single user to root.                                                                                                                                                                                                 |

3. Verify that the option is set to the desired value: `vserver cifs options show -vserver vserver_name`
4. Return to the admin privilege level: `set -privilege admin`

## Display information about what types of users are connected over SMB sessions

You can display information about what type of users are connected over SMB sessions. This can help you ensure that only the appropriate type of user is connecting over SMB sessions on the storage virtual machine (SVM).

## About this task

The following types of users can connect over SMB sessions:

- local-user

Authenticated as a local CIFS user

- domain-user

Authenticated as a domain user (either from the CIFS server's home domain or a trusted domain)

- guest-user

Authenticated as a guest user

- anonymous-user

Authenticated as an anonymous or null user

## Steps

1. Determine what type of user is connected over an SMB session: `vserver cifs session show -vserver vserver_name -windows-user windows_user_name -fields windows-user,address,lif-address,user-type`

| If you want to display user type information for established sessions... | Enter the following command...                                                                                                                  |
|--------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------|
| For all sessions with a specified user type                              | <code>vserver cifs session show -vserver vserver_name -user-type {local-user domain-user guest-user anonymous-user}</code>                      |
| For a specific user                                                      | <code>vserver cifs session show -vserver vserver_name -windows-user windows_user_name -fields windows-user,address,lif-address,user-type</code> |

## Examples

The following command displays session information on the user type for sessions on SVM vs1 established by user "``iepubs\user1``":

```
cluster1::> vserver cifs session show -vserver pub1 -windows-user
iepubs\user1 -fields windows-user,address,lif-address,user-type
node vserver session-id connection-id lif-address address
windows-user user-type

pub1node1 pub1 1 3439441860 10.0.0.1 10.1.1.1
IEPUBS\user1 domain-user
```

## Command options to limit excessive Windows client resource consumption

Options to the `vserver cifs` options modify command enable you to control resource consumption for Windows clients. This can be helpful if any clients are outside normal bounds of resource consumption, for example, if there are unusually high numbers of files open, sessions open, or change notify requests.

The following options to the `vserver cifs` options modify command have been added to control Windows client resource consumption. If the maximum value for any of these options is exceeded, the request is denied and an EMS message is sent. An EMS warning message is also sent when 80 percent of the configured limit for these options is reached.

- `-max-opens-same-file-per-tree`  
Maximum number of opens on the same file per CIFS tree
- `-max-same-user-sessions-per-connection`  
Maximum number of sessions opened by the same user per connection
- `-max-same-tree-connect-per-session`  
Maximum number of tree connects on the same share per session
- `-max-watches-set-per-tree`  
Maximum number of watches (also known as *change notifies*) established per tree

See the man pages for the default limits and to display the current configuration.

Beginning with ONTAP 9.4, servers running SMB version 2 or later can limit the number of outstanding requests (*SMB credits*) that the client can send to the server on a SMB connection. The management of SMB credits is initiated by the client and controlled by the server.

The maximum number of outstanding requests that can be granted on an SMB connection is controlled by the `-max-credits` option. The default value for this option is 128.

## **Improve client performance with traditional and lease oplocks**

### **Improve client performance with traditional and lease oplocks overview**

Traditional oplocks (opportunistic locks) and lease oplocks enable an SMB client in certain file-sharing scenarios to perform client-side caching of read-ahead, write-behind, and lock information. A client can then read from or write to a file without regularly reminding the server that it needs access to the file in question. This improves performance by reducing network traffic.

Lease oplocks are an enhanced form of oplocks available with the SMB 2.1 protocol and later. Lease oplocks allow a client to obtain and preserve client caching state across multiple SMB opens originating from itself.

Oplocks can be controlled in two ways:

- By a share property, using the `vserver cifs share create` command when the share is created, or the `vserver share properties` command after creation.
- By a qtree property, using the `volume qtree create` command when the qtree is created, or the `volume qtree oplock` commands after creation.

### **Write cache data-loss considerations when using oplocks**

Under some circumstances, if a process has an exclusive oplock on a file and a second process attempts to open the file, the first process must invalidate cached data and flush writes and locks. The client must then relinquish the oplock and access to the file. If there is a network failure during this flush, cached write data might be lost.

- Data-loss possibilities

Any application that has write-cached data can lose that data under the following set of circumstances:

- The connection is made using SMB 1.0.
- It has an exclusive oplock on the file.
- It is told to either break that oplock or close the file.
- During the process of flushing the write cache, the network or target system generates an error.

- Error handling and write completion

The cache itself does not have any error handling—the applications do. When the application makes a write to the cache, the write is always completed. If the cache, in turn, makes a write to the target system over a network, it must assume that the write is completed because if it does not, the data is lost.

#### **Enable or disable oplocks when creating SMB shares**

Oplocks allow clients to lock files and cache content locally, which can increase performance for file operations. Oplocks are enabled on SMB shares residing on storage virtual machines (SVMs). In some circumstances, you might want to disable oplocks. You can enable or disable oplocks on a share-by-share basis.

#### **About this task**

If oplocks are enabled on the volume containing a share but the oplock share property for that share is disabled, oplocks are disabled for that share. Disabling oplocks on a share takes precedence over the volume oplock setting. Disabling oplocks on the share disables both opportunistic and lease oplocks.

You can specify other share properties in addition to specifying the oplock share property by using a comma-delimited list. You can also specify other share parameters.

#### **Steps**

1. Perform the applicable action:

| If you want to...                                | Then...                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|--------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Enable oplocks on a share during share creation  | <p>Enter the following command:</p> <pre>vserver cifs share create -vserver _vserver_name_ -share-name share_name -path path_to_share -share-properties [oplocks,...]</pre> <p> If you want the share to have only the default share properties, which are oplocks, browsable, and changenotify enabled, you do not have to specify the -share-properties parameter when creating an SMB share. If you want any combination of share properties other than the default, then you must specify the -share-properties parameter with the list of share properties to use for that share.</p> |
| Disable oplocks on a share during share creation | <p>Enter the following command:</p> <pre>vserver cifs share create -vserver _vserver_name_ -share-name _share_name_ -path _path_to_share_ -share-properties [other_share_property,...]</pre> <p> When disabling oplocks, you must specify a list of share properties when creating the share, but you should not specify the oplocks property.</p>                                                                                                                                                                                                                                       |

### Commands for enabling or disabling oplocks on volumes and qtrees

Oplocks allow clients to lock files and cache content locally, which can increase performance for file operations. You need to know the commands for enabling or disabling oplocks on volumes or qtrees. You also must know when you can enable or disable oplocks on volumes and qtrees.

- Oplocks are enabled on volumes by default.
- You cannot disable oplocks when you create a volume.
- You can enable or disable oplocks on existing volumes for SVMs at any time.

- You can enable oplocks on qtrees for SVMs.

The oplock mode setting is a property of qtree ID 0, the default qtree that all volumes have. If you do not specify an oplock setting when creating a qtree, the qtree inherits the oplock setting of the parent volume, which is enabled by default. However, if you do specify an oplock setting on the new qtree, it takes precedence over the oplock setting on the volume.

| If you want to...                    | Use this command...                                                              |
|--------------------------------------|----------------------------------------------------------------------------------|
| Enable oplocks on volumes or qtrees  | <code>volume qtree oplocks with the -oplock-mode parameter set to enable</code>  |
| Disable oplocks on volumes or qtrees | <code>volume qtree oplocks with the -oplock-mode parameter set to disable</code> |

### Enable or disable oplocks on existing SMB shares

Oplocks are enabled on SMB shares on storage virtual machines (SVMs) by default. Under some circumstances, you might want to disable oplocks; alternatively, if you have previously disabled oplocks on a share, you might want to reenable oplocks.

#### About this task

If oplocks are enabled on the volume containing a share, but the oplock share property for that share is disabled, oplocks are disabled for that share. Disabling oplocks on a share takes precedence over enabling oplocks on the volume. Disabling oplocks on the share, disables both opportunistic and lease oplocks. You can enable or disable oplocks on existing shares at any time.

#### Step

1. Perform the applicable action:

| If you want to...                                        | Then...                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
|----------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Enable oplocks on a share by modifying an existing share | <p>Enter the following command:</p> <pre>vserver cifs share properties add -vserver vserver_name -share-name share_name -share-properties oplocks</pre> <p> You can specify additional share properties to add by using a comma-delimited list.</p> <p>Newly added properties are appended to the existing list of share properties. Any share properties that you have previously specified remain in effect.</p> |

| If you want to...                                         | Then...                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
|-----------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Disable oplocks on a share by modifying an existing share | <p>Enter the following command: <code>vserver cifs share properties remove -vserver vserver_name -share-name share_name -share-properties oplocks</code></p> <p> You can specify additional share properties to remove by using a comma-delimited list.</p> <p>Share properties that you remove are deleted from the existing list of share properties; however, previously configured share properties that you do not remove remain in effect.</p> |

## Examples

The following command enables oplocks for the share named “Engineering” on storage virtual machine (SVM, formerly known as Vserver) vs1:

```
cluster1::> vserver cifs share properties add -vserver vs1 -share-name Engineering -share-properties oplocks

cluster1::> vserver cifs share properties show
Vserver Share Properties

vs1 Engineering oplocks
 browsable
 changenotify
 showsnapshot
```

The following command disables oplocks for the share named “Engineering” on SVM vs1:

```
cluster1::> vserver cifs share properties remove -vserver vs1 -share-name Engineering -share-properties oplocks

cluster1::> vserver cifs share properties show
Vserver Share Properties

vs1 Engineering browsable
 changenotify
 showsnapshot
```

## Related information

[Enabling or disabling oplocks when creating SMB shares](#)

## [Monitoring oplock status](#)

### [Adding or removing share properties on an existing SMB share](#)

#### **Monitor oplock status**

You can monitor and display information about oplock status. You can use this information to determine which files have oplocks, what the oplock level and oplock state level are, and whether oplock leasing is used. You can also determine information about locks that you might need to break manually.

#### **About this task**

You can display information about all oplocks in summary form or in a detailed list form. You can also use optional parameters to display information about a smaller subset of existing locks. For example, you can specify that the output return only locks with the specified client IP address or with the specified path.

You can display the following information about traditional and lease oplocks:

- SVM, node, volume, and LIF on which the oplock is established
- Lock UUID
- IP address of the client with the oplock
- Path at which the oplock is established
- Lock protocol (SMB) and type (oplock)
- Lock state
- Oplock level
- Connection state and SMB expiration time
- Open Group ID if a lease oplock is granted

See the `vserver oplocks show` man page for a detailed description of each parameter.

#### **Steps**

1. Display oplock status by using the `vserver locks show` command.

#### **Examples**

The following command displays default information about all locks. The oplock on the displayed file is granted with a `read-batch` oplock level:

```
cluster1::> vserver locks show

Vserver: vs0
Volume Object Path LIF Protocol Lock Type Client
----- -----
vol1 /vol1/notes.txt node1_data1
 cifs share-level 192.168.1.5
 Sharelock Mode: read_write-deny_delete
 op-lock 192.168.1.5
 Ooplock Level: read-batch
```

The following example displays more detailed information about the lock on a file with the path /data2/data2\_2/intro.pptx. A lease oplock is granted on the file with a batch oplock level to a client with an IP address of 10.3.1.3:

When displaying detailed information, the command provides separate output for oplock and sharelock information. This example only shows the output from the oplock section.

```
cluster1::> vserver lock show -instance -path /data2/data2_2/intro.pptx

 Vserver: vs1
 Volume: data2_2
Logical Interface: lif2
 Object Path: /data2/data2_2/intro.pptx
 Lock UUID: ff1cbf29-bfef-4d91-ae06-062bf69212c3
 Lock Protocol: cifs
 Lock Type: op-lock
Node Holding Lock State: node3
 Lock State: granted
Bytelock Starting Offset: -
 Number of Bytes Locked: -
 Bytelock is Mandatory: -
 Bytelock is Exclusive: -
 Bytelock is Superlock: -
 Bytelock is Soft: -

## Apply Group Policy Objects to SMB servers

### Apply Group Policy Objects to SMB servers overview

Your SMB server supports Group Policy Objects (GPOs), a set of rules known as *group policy attributes* that apply to computers in an Active Directory environment. You can use GPOs to centrally manage settings for all storage virtual machines (SVMs) on the cluster belonging to the same Active Directory domain.

When GPOs are enabled on your SMB server, ONTAP sends LDAP queries to the Active Directory server requesting GPO information. If there are GPO definitions that are applicable to your SMB server, the Active Directory server returns the following GPO information:

- GPO name
- Current GPO version
- Location of the GPO definition
- Lists of UUIDs (universally unique identifiers) for GPO policy sets

## Related information

[Securing file access by using Dynamic Access Control \(DAC\)](#)

[SMB and NFS auditing and security tracing](#)

## Supported GPOs

Although not all Group Policy Objects (GPOs) are applicable to your CIFS-enabled storage virtual machines (SVMs), SVMs can recognize and process the relevant set of GPOs.

The following GPOs are currently supported on SVMs:

- Advanced audit policy configuration settings:

Object access: Central Access Policy staging

Specifies the type of events to be audited for central access policy (CAP) staging, including the following settings:

- Do not audit
- Audit only success events
- Audit only failure events
- Audit both success and failure events

If any of the three audit options are set (audit only success events, audit only failure events, audit both success and failure events), ONTAP audits both success and failure events.

Set by using the Audit Central Access Policy Staging setting in the Advanced Audit Policy Configuration/Audit Policies/Object Access GPO.

To use advanced audit policy configuration GPO settings, auditing must be configured on the CIFS-enabled SVM to which you want to apply these setting. If auditing is not configured on the SVM, the GPO settings will not be applied and will be dropped.

- Registry settings:

- Group Policy refresh interval for CIFS-enabled SVM

Set by using the Registry GPO.

- Group Policy refresh random offset

Set by using the Registry GPO.

- Hash publication for BranchCache

The Hash Publication for BranchCache GPO corresponds to the BranchCache operating mode. The following three supported operating modes are supported:

- Per-share
- All-shares
- Disabled  
Set by using the Registry GPO.

- Hash version support for BranchCache

The following three hash version settings are supported:

- BranchCache version 1
- BranchCache version 2
- BranchCache versions 1 and 2  
Set by using the Registry GPO.

To use BranchCache GPO settings, BranchCache must be configured on the CIFS-enabled SVM to which you want to apply these setting. If BranchCache is not configured on the SVM, the GPO settings will not be applied and will be dropped.

- Security settings

- Audit policy and event log

- Audit logon events

Specifies the type of logon events to be audited, including the following settings:

- Do not audit
- Audit only success events
- Audit on failure events
- Audit both success and failure events

Set by using the Audit logon events setting in the Local Policies/Audit Policy GPO.

If any of the three audit options are set (audit only success events, audit only failure events, audit both success and failure events), ONTAP audits both success and failure events.

- Audit object access

Specifies the type of object access to be audited, including the following settings:

- Do not audit
- Audit only success events
- Audit on failure events
- Audit both success and failure events

Set by using the Audit object access setting in the Local Policies/Audit Policy GPO.

If any of the three audit options are set (audit only success events, audit only failure events, audit both success and failure events), ONTAP audits both success and failure events.

- Log retention method

Specifies the audit log retention method, including the following settings:

- Overwrite the event log when size of the log file exceeds the maximum log size
  - Do not overwrite the event log (clear log manually)
- Set by using the Retention method for security log setting in the Event Log GPO.

- Maximum log size

Specifies the maximum size of the audit log.

Set by using the Maximum security log size setting in the Event Log GPO.

To use audit policy and event log GPO settings, auditing must be configured on the CIFS-enabled SVM to which you want to apply these setting. If auditing is not configured on the SVM, the GPO settings will not be applied and will be dropped.

- File system security

Specifies a list of files or directories on which file security is applied through a GPO.

Set by using the File System GPO.

The volume path to which the file system security GPO is configured must exist within the SVM.

- Kerberos policy

- Maximum clock skew

Specifies maximum tolerance in minutes for computer clock synchronization.

Set by using the Maximum tolerance for computer clock synchronization setting in the Account Policies/Kerberos Policy GPO.

- Maximum ticket age

Specifies maximum lifetime in hours for user ticket.

Set by using the Maximum lifetime for user ticket setting in the Account Policies/Kerberos Policy GPO.

- Maximum ticket renew age

Specifies maximum lifetime in days for user ticket renewal.

Set by using the Maximum lifetime for user ticket renewal setting in the Account Policies/Kerberos Policy GPO.

- User rights assignment (privilege rights)

- Take ownership

Specifies the list of users and groups that have the right to take ownership of any securable object.

Set by using the Take ownership of files or other objects setting in the Local Policies/User Rights Assignment GPO.

- Security privilege

Specifies the list of users and groups that can specify auditing options for object access of individual resources, such as files, folders, and Active Directory objects.

Set by using the Manage auditing and security log setting in the Local Policies/User Rights Assignment GPO.

- Change notify privilege (bypass traverse checking)

Specifies the list of users and groups that can traverse directory trees even though the users and groups might not have permissions on the traversed directory.

The same privilege is required for users to receive notifications of changes to files and directories.  
Set by using the Bypass traverse checking setting in the Local Policies/User Rights Assignment GPO.

- Registry values

- Signing required setting

Specifies whether required SMB signing is enabled or disabled.

Set by using the Microsoft network server: Digitally sign communications (always) setting in the Security Options GPO.

- Restrict anonymous

Specifies what the restrictions for anonymous users are and includes the following three GPO settings:

- No enumeration of Security Account Manager (SAM) accounts:

This security setting determines what additional permissions are granted for anonymous connections to the computer. This option is displayed as no-enumeration in ONTAP if it is enabled.

Set by using the Network access: Do not allow anonymous enumeration of SAM accounts setting in the Local Policies/Security Options GPO.

- No enumeration of SAM accounts and shares

This security setting determines whether anonymous enumeration of SAM accounts and shares is allowed. This option is displayed as no-enumeration in ONTAP if it is enabled.

**Set by using the Network access:** Do not allow anonymous enumeration of SAM accounts and shares **setting in the Local Policies/Security Options GPO.**

- Restrict anonymous access to shares and named pipes

This security setting restricts anonymous access to shares and pipes. This option is displayed as no-access in ONTAP if it is enabled.

**Set by using the Network access:** Restrict anonymous access to Named Pipes and Shares **setting in the Local Policies/Security Options GPO.**

When displaying information about defined and applied group policies, the Resultant restriction for anonymous user output field provides information about the resultant restriction of the three restrict anonymous GPO settings. The possible resultant restrictions are as follows:

- no-access

The anonymous user is denied access to the specified shares and named pipes, and cannot use enumeration of SAM accounts and shares. This resultant restriction is seen if the Network access : Restrict anonymous access to Named Pipes and Shares GPO is enabled.

- no-enumeration

The anonymous user has access to the specified shares and named pipes, but cannot use enumeration of SAM accounts and shares. This resultant restriction is seen if both of the following conditions are met:

- The Network access: Restrict anonymous access to Named Pipes and Shares GPO is disabled.
- Either the Network access: Do not allow anonymous enumeration of SAM accounts or the Network access: Do not allow anonymous enumeration of SAM accounts and shares GPOs is enabled.

- no-restriction

The anonymous user has full access and can use enumeration. This resultant restriction is seen if both of the following conditions are met:

- The Network access: Restrict anonymous access to Named Pipes and Shares GPO is disabled.
- Both the Network access: Do not allow anonymous enumeration of SAM accounts and Network access: Do not allow anonymous enumeration of SAM accounts and shares GPOs are disabled.
  - Restricted Groups

You can configure restricted groups to centrally manage membership of either built-in or user-defined groups. When you apply a restricted group through a group policy, the membership of a CIFS server local group is automatically set to match the membership-list settings defined in the applied group policy.

**Set by using the Restricted Groups GPO.**

- Central access policy settings

Specifies a list of central access policies. Central access policies and the associated central access policy rules determine access permissions for multiple files on the SVM.

## Requirements for using GPOs with your SMB server

To use Group Policy Objects (GPOs) with your SMB server, your system must meet several requirements.

- SMB must be licensed on the cluster.
- A SMB server must be configured and joined to a Windows Active Directory domain.
- The SMB server admin status must be on.
- GPOs must be configured and applied to the Windows Active Directory Organizational Unit (OU) containing the SMB server computer object.
- GPO support must be enabled on the SMB server.

## Enable or disable GPO support on a CIFS server

You can enable or disable Group Policy Object (GPO) support on a CIFS server. If you enable GPO support on a CIFS server, the applicable GPOs that are defined on the group policy—the policy that is applied to the organizational unit (OU) that contains the CIFS server computer object—are applied to the CIFS server.

### About this task

GPOs cannot be enabled on CIFS servers in workgroup mode.

## Steps

1. Perform one of the following actions:

| If you want to... | Enter the command...                                                              |
|-------------------|-----------------------------------------------------------------------------------|
| Enable GPOs       | vserver cifs group-policy modify<br>-vserver <i>vserver_name</i> -status enabled  |
| Disable GPOs      | vserver cifs group-policy modify<br>-vserver <i>vserver_name</i> -status disabled |

2. Verify that GPO support is in the desired state: `vserver cifs group-policy show -vserver +vserver_name`

Group Policy Status for CIFS servers in workgroup mode is displayed as “disabled”.

### Example

The following example enables GPO support on storage virtual machine (SVM) vs1:

```
cluster1::> vserver cifs group-policy modify -vserver vs1 -status enabled

cluster1::> vserver cifs group-policy show -vserver vs1

 Vserver: vs1
Group Policy Status: enabled
```

#### [Displaying information about GPO configurations](#)

#### [How GPOs are updated on the SMB server](#)

#### [How GPOs are updated on the CIFS server overview](#)

By default, ONTAP retrieves and applies Group Policy Object (GPO) changes every 90 minutes. Security settings are refreshed every 16 hours. If you want to update GPOs to apply new GPO policy settings before ONTAP automatically updates them, you can trigger a manual update on a CIFS server with an ONTAP command.

- By default, all GPOs are verified and updated as needed every 90 minutes.

This interval is configurable and can be set using the Refresh interval and Random offset GPO settings.

ONTAP queries Active Directory for changes to GPOs. If the GPO version numbers recorded in Active

Directory are higher than those on the CIFS server, ONTAP retrieves and applies the new GPOs. If the version numbers are the same, GPOs on the CIFS server are not updated.

- Security Settings GPOs are refreshed every 16 hours.

ONTAP retrieves and applies Security Settings GPOs every 16 hours, whether or not these GPOs have changed.

The 16-hour default value cannot be changed in the current ONTAP version. It is a Windows client default setting.

- All GPOs can be updated manually with an ONTAP command.

This command simulates the Windows `gpupdate.exe `/force`` command.

## What to do if GPO updates are failing

Under some circumstances, Group Policy Object (GPO) updates from Windows 2012 domain controllers might fail, which leads to nothing being visible under the Central Access Policy Settings section of the output for the `vserver cifs group-policy show-defined` command. You should know how to correct this issue if it occurs.

| Underlying cause                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   | Remedy                                                                                                                                                                                                                                                                                                                                                                                                                                              |
|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <p>When ONTAP attempts to connect to the Windows 2012 domain controller to perform the GPO update, the connection might fail with the error <code>error 0xc00000bd (NT STATUS_DUPLICATE_NAME)</code>.</p> <p>This error occurs when the server name used to make the connection is different from the NetBIOS name of the CIFS server. There are various reasons this might occur, including the use of aliases. Additionally, ONTAP pads the NetBIOS name used when connecting to the domain controller to make the name length equal to 15 characters. This can make it appear that the CIFS server name and the NetBIOS name are different.</p> | <ol style="list-style-type: none"><li>1. Disable NetBIOS name checking on the Windows server by adding the following registry key with the value set to 1:<br/><code>"HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\LanmanServer\Parameters\DisableStrictNameChecking"</code><br/>To learn more about this registry key, contact Microsoft Support.<br/><a href="#">Microsoft Support</a></li><li>2. Reboot the domain controller.</li></ol> |

[Manually updating GPO settings on the CIFS server](#)

If you want to update Group Policy Object (GPO) settings on your CIFS server immediately, you can manually update the settings. You can update only changed settings or you can force an update for all settings, including the settings that were applied previously but have not changed.

## Step

1. Perform the appropriate action:

| If you want to update... | Enter the command...                                                                           |
|--------------------------|------------------------------------------------------------------------------------------------|
| Changed GPO settings     | vserver cifs group-policy update<br>-vserver vserver_name                                      |
| All GPO settings         | vserver cifs group-policy update<br>-vserver vserver_name -force-reapply<br>-all-settings true |

## Related information

## Related information

[Enabling or disabling GPO support on a CIFS server](#)

[Display detailed information about restricted group GPOs](#)

You can display detailed information about restricted groups that are defined as Group Policy Objects (GPOs) in Active Directory and that are applied to the CIFS server.

## About this task

By default, the following information is displayed:

- Group policy name
- Group policy version

- **Link**

Specifies the level in which the group policy is configured. Possible output values include the following:

- Local when the group policy is configured in ONTAP
- Site when the group policy is configured at the site level in the domain controller
- Domain when the group policy is configured at the domain level in the domain controller
- OrganizationalUnit when the group policy is configured at the Organizational Unit (OU) level in the domain controller
- RSOP for the resultant set of policies derived from all the group policies defined at various levels

- Restricted group name
- The users and groups who belong to and who do not belong to the restricted group
- The list of groups to which the restricted group is added

A group can be a member of groups other than the groups listed here.

### Step

1. Display information about all restricted group GPOs by performing one of the following actions:

| If you want to display information about all restricted group GPOs... | Enter the command...                                                                       |
|-----------------------------------------------------------------------|--------------------------------------------------------------------------------------------|
| Defined in Active Directory                                           | <code>vserver cifs group-policy restricted-group show-defined -vserver vserver_name</code> |
| Applied to a CIFS server                                              | <code>vserver cifs group-policy restricted-group show-applied -vserver vserver_name</code> |

### Example

The following example displays information about restricted group GPOs defined in the Active Directory domain to which the CIFS-enabled SVM named vs1 belongs:

```
cluster1::> vserver cifs group-policy restricted-group show-defined
-vserver vs1

Vserver: vs1

 Group Policy Name: gpo1
 Version: 16
 Link: OrganizationalUnit
 Group Name: group1
 Members: user1
 MemberOf: EXAMPLE\group9

 Group Policy Name: Resultant Set of Policy
 Version: 0
 Link: RSOP
 Group Name: group1
 Members: user1
 MemberOf: EXAMPLE\group9
```

The following example displays information about restricted groups GPOs applied to the CIFS-enabled SVM vs1:

```
cluster1::> vserver cifs group-policy restricted-group show-applied
-vserver vs1

Vserver: vs1

 Group Policy Name: gpo1
 Version: 16
 Link: OrganizationalUnit
 Group Name: group1
 Members: user1
 MemberOf: EXAMPLE\group9

 Group Policy Name: Resultant Set of Policy
 Version: 0
 Link: RSOP
 Group Name: group1
 Members: user1
 MemberOf: EXAMPLE\group9
```

## Related information

## Displaying information about GPO configurations

### Display information about central access policies

You can display detailed information about the central access policies that are defined in Active Directory. You can also display information about the central access policies that are applied to the CIFS server through group policy objects (GPOs).

#### About this task

By default, the following information is displayed:

- SVM name
- Name of the central access policy
- SID
- Description
- Creation time
- Modification time
- Member rules

CIFS servers in workgroup mode are not displayed because they do not support GPOs.

#### Step

1. Display information about central access policies by performing one of the following actions:

| If you want to display information about all central access policies... | Enter the command...                                                                                   |
|-------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------|
| Defined in Active Directory                                             | <code>vserver cifs group-policy central-access-policy show-defined -vserver <i>vserver_name</i></code> |
| Applied to a CIFS server                                                | <code>vserver cifs group-policy central-access-policy show-applied -vserver <i>vserver_name</i></code> |

#### Example

The following example displays information for all the central access policies that are defined in Active Directory:

```

cluster1::> vserver cifs group-policy central-access-policy show-defined

Vserver Name SID

### [Displaying information about GPO configurations](#)

### [Displaying information about central access policy rules](#)

#### **Display information about central access policy rules**

You can display detailed information about central access policy rules that are associated with central access policies defined in Active Directory. You can also display information about central access policies rules that are applied to the CIFS server through central access policy GPOs (group policy objects).

#### **About this task**

You can display detailed information about defined and applied central access policy rules. By default, the following information is displayed:

- Vserver name
- Name of the central access rule
- Description
- Creation time
- Modification time
- Current permissions
- Proposed permissions
- Target resources

**Table 1. Step**

| If you want to display information about all central access policy rules associated with central access policies... | Enter the command...                                                                          |
|---------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------|
| Defined in Active Directory                                                                                         | <code>vserver cifs group-policy central-access-rule show-defined -vserver vserver_name</code> |
| Applied to a CIFS server                                                                                            | <code>vserver cifs group-policy central-access-rule show-applied -vserver vserver_name</code> |

#### **Example**

The following example displays information for all central access policy rules associated with central access policies defined in Active Directory:

```

cluster1::> vserver cifs group-policy central-access-rule show-defined

Vserver Name

vs1 r1
 Description: rule #1
 Creation Time: Tue Oct 22 09:33:48 2013
 Modification Time: Tue Oct 22 09:33:48 2013
 Current Permissions: O:SYG:SYD:AR(A;;FA;;;WD)
 Proposed Permissions: O:SYG:SYD:(A;;FA;;;OW) (A;;FA;;;BA) (A;;FA;;;SY)

vs1 r2
 Description: rule #2
 Creation Time: Tue Oct 22 10:27:57 2013

## Commands for managing SMB servers computer account passwords

You need to know the commands for changing, resetting, and disabling passwords, and for configuring automatic update schedules. You can also configure a schedule on the SMB server to update it automatically.

| If you want to...                                                     | Use this command...                                                                          |
|-----------------------------------------------------------------------|----------------------------------------------------------------------------------------------|
| Change or reset the domain account password and you know the password | vserver cifs domain password change                                                          |
| Reset the domain account password and you do not know the password    | vserver cifs domain password reset                                                           |
| Configure SMB servers for automatic computer account password changes | vserver cifs domain password schedule modify -vserver vserver_name -is-schedule-enabled true |
| Disable automatic computer account password changes on SMB servers    | vserver cifs domain password schedule modify -vserver vs1 -is-schedule-enabled false         |

See the man page for each command for more information.

## Manage domain controller connections

### Display information about discovered servers

You can display information related to discovered LDAP servers and domain controllers on your CIFS server.

#### Step

1. To display information related to discovered servers, enter the following command: `vserver cifs domain discovered-servers show`

#### Example

The following example shows discovered servers for SVM vs1:

```
cluster1::> vserver cifs domain discovered-servers show
```

Node: node1

Vserver: vs1

| Domain Name | Type    | Preference | DC-Name | DC-Address | Status |
|-------------|---------|------------|---------|------------|--------|
| example.com | MS-LDAP | adequate   | DC-1    | 1.1.3.4    | OK     |
| example.com | MS-LDAP | adequate   | DC-2    | 1.1.3.5    | OK     |
| example.com | MS-DC   | adequate   | DC-1    | 1.1.3.4    | OK     |
| example.com | MS-DC   | adequate   | DC-2    | 1.1.3.5    | OK     |

## Related information

[Resetting and rediscovering servers](#)

[Stopping or starting the CIFS server](#)

### Reset and rediscover servers

Resetting and rediscovering servers on your CIFS server allows the CIFS server to discard stored information about LDAP servers and domain controllers. After discarding server information, the CIFS server reacquires current information about these external servers. This can be useful when the connected servers are not responding appropriately.

### Steps

1. Enter the following command: `vserver cifs domain discovered-servers reset-servers -vserver vserver_name`
2. Display information about the newly rediscovered servers: `vserver cifs domain discovered-servers show -vserver vserver_name`

### Example

The following example resets and redisCOVERS servers for storage virtual machine (SVM, formerly known as Vserver) vs1:

```

cluster1::> vserver cifs domain discovered-servers reset-servers -vserver
vs1

cluster1::> vserver cifs domain discovered-servers show

Node: node1
Vserver: vs1

Domain Name Type Preference DC-Name DC-Address Status
----- ----- ----- ----- ----- -----
example.com MS-LDAP adequate DC-1 1.1.3.4 OK
example.com MS-LDAP adequate DC-2 1.1.3.5 OK
example.com MS-DC adequate DC-1 1.1.3.4 OK
example.com MS-DC adequate DC-2 1.1.3.5 OK

```

## Related information

[Displaying information about discovered servers](#)

[Stopping or starting the CIFS server](#)

[Manage domain controller discovery](#)

Beginning with ONTAP 9.3, you can modify the default process by which domain controllers (DCs) are discovered. This enables you to limit discovery to your site or to a pool of preferred DCs, which can lead to performance improvements depending on the environment.

### About this task

By default, the dynamic discovery process discovers all available DCs, including any preferred DCs, all DCs in the local site, and all remote DCs. This configuration can lead to latency in authentication and accessing shares in certain environments. If you have already determined the pool of DCs that you want to use, or if the remote DCs are inadequate or inaccessible, you can change the discovery method.

In ONTAP 9.3 and later releases, the `discovery-mode` parameter of the `cifs domain discovered-servers` command enables you to select one of the following discovery options:

- All DCs in the domain are discovered.
- Only DCs in the local site are discovered.

The `default-site` parameter for the SMB server must be defined to use this mode.

- Server discovery is not performed, the SMB server configuration depends only on preferred DCs.

To use this mode, you must first define the preferred DCs for the SMB server.

### Step

1. Specify the desired discovery option: `vserver cifs domain discovered-servers discovery-mode modify -vserver vserver_name -mode {all|site|none}`

Options for the mode parameter:

◦ all

Discover all available DCs (default).

◦ site

Limit DC discovery to your site.

◦ none

Use only preferred DCs and not perform discovery.

#### Add preferred domain controllers

ONTAP automatically discovers domain controllers through DNS. Optionally, you can add one or more domain controllers to the list of preferred domain controllers for a specific domain.

#### About this task

If a preferred domain controller list already exists for the specified domain, the new list is merged with the existing list.

#### Step

1. To add to the list of preferred domain controllers, enter the following command:

```
vserver cifs domain preferred-dc add -vserver vserver_name -domain domain_name
-preferred-dc IP_address, ...+
```

`-vserver vserver_name` specifies the storage virtual machine (SVM) name.

`-domain domain_name` specifies the fully qualified Active Directory name of the domain to which the specified domain controllers belong.

`-preferred-dc IP_address,...` specifies one or more IP addresses of the preferred domain controllers, as a comma-delimited list, in order of preference.

#### Example

The following command adds domain controllers 172.17.102.25 and 172.17.102.24 to the list of preferred domain controllers that the SMB server on SVM vs1 uses to manage external access to the `cifs.lab.example.com` domain.

```
cluster1::> vserver cifs domain preferred-dc add -vserver vs1 -domain
cifs.lab.example.com -preferred-dc 172.17.102.25,172.17.102.24
```

#### Related information

[Commands for managing preferred domain controllers](#)

## Commands for managing preferred domain controllers

You need to know the commands for adding, displaying, and removing preferred domain controllers.

| If you want to...                    | Use this command...                     |
|--------------------------------------|-----------------------------------------|
| Add a preferred domain controller    | vserver cifs domain preferred-dc add    |
| Display preferred domain controllers | vserver cifs domain preferred-dc show   |
| Remove a preferred domain controller | vserver cifs domain preferred-dc remove |

See the man page for each command for more information.

### Related information

[Adding preferred domain controllers](#)

### Enable SMB2 connections to domain controllers

Beginning with ONTAP 9.1, you can enable SMB version 2.0 to connect to a domain controller. Doing so is necessary if you have disabled SMB 1.0 on domain controllers. Beginning with ONTAP 9.2, SMB2 is enabled by default.

### About this task

The `smb2-enabled-for-dc-connections` command option enables the system default for the release of ONTAP you are using. The system default for ONTAP 9.1 is enabled for SMB 1.0 and disabled for SMB 2.0. The system default for ONTAP 9.2 is enabled for SMB 1.0 and enabled for SMB 2.0. If the domain controller cannot negotiate SMB 2.0 initially, it uses SMB 1.0.

SMB 1.0 can be disabled from ONTAP to a domain controller. In ONTAP 9.1, if SMB 1.0 has been disabled, SMB 2.0 must be enabled in order to communicate with a domain controller.

Learn more about:

- [Verifying enabled SMB versions.](#)
- [Supported SMB versions and functionality.](#)

If `-smb1-enabled-for-dc-connections` is set to `false` while `-smb1-enabled` is set to `true`, ONTAP denies SMB 1.0 connections as the client, but continues to accept inbound SMB 1.0 connections as the server.

### Steps

1. Before changing SMB security settings, verify which SMB versions are enabled: `vserver cifs security show`
2. Scroll down the list to see the SMB versions.
3. Perform the appropriate command, using the `smb2-enabled-for-dc-connections` option.

| If you want SMB2 to be... | Enter the command...                                                                              |
|---------------------------|---------------------------------------------------------------------------------------------------|
| Enabled                   | vserver cifs security modify -vserver <i>vserver_name</i> -smb2-enabled-for-dc -connections true  |
| Disabled                  | vserver cifs security modify -vserver <i>vserver_name</i> -smb2-enabled-for-dc -connections false |

#### Enable encrypted connections to domain controllers

Beginning with ONTAP 9.8, you can specify that connections to domain controllers be encrypted.

#### About this task

ONTAP requires encryption for domain controller (DC) communications when the `-encryption-required-for-dc-connection` option is set to `true`; the default is `false`. When the option is set, only the SMB3 protocol will be used for ONTAP-DC connections, because encryption is only supported by SMB3.

When encrypted DC communications are required, the `-smb2-enabled-for-dc-connections` option is ignored, because ONTAP only negotiates SMB3 connections. If a DC doesn't support SMB3 and encryption, ONTAP will not connect with it.

#### Step

1. Enable encrypted communication with the DC: `vserver cifs security modify -vserver svm_name -encryption-required-for-dc-connection true`

#### Use null sessions to access storage in non-Kerberos environments

##### Use null sessions to access storage in non-Kerberos environments overview

Null session access provides permissions for network resources, such as storage system data, and to client-based services running under the local system. A null session occurs when a client process uses the “system” account to access a network resource. Null session configuration is specific to non-Kerberos authentication.

##### How the storage system provides null session access

Because null session shares do not require authentication, clients that require null session access must have their IP addresses mapped on the storage system.

By default, unmapped null session clients can access certain ONTAP system services, such as share enumeration, but they are restricted from accessing any storage system data.

ONTAP supports Windows RestrictAnonymous registry setting values with the `-restrict-anonymous` option. This enables you to control the extent to which unmapped null users can view or access system resources. For example, you can disable share enumeration and access to the IPC\$ share (the hidden named pipe share). The `vserver cifs options modify` and `vserver cifs options show` man pages provide more information about the `-restrict-anonymous` option.

Unless otherwise configured, a client running a local process that requests storage system access through a null session is a member only of nonrestrictive groups, such as “everyone”. To limit null session access to selected storage system resources, you might want to create a group to which all null session clients belong; creating this group enables you to restrict storage system access and to set storage system resource permissions that apply specifically to null session clients.

ONTAP provides a mapping syntax in the `vserver name-mapping` command set to specify the IP address of clients allowed access to storage system resources using a null user session. After you create a group for null users, you can specify access restrictions for storage system resources and resource permissions that apply only to null sessions. Null user is identified as anonymous logon. Null users do not have access to any home directory.

Any null user accessing the storage system from a mapped IP address is granted mapped user permissions. Consider appropriate precautions to prevent unauthorized access to storage systems mapped with null users. For maximum protection, place the storage system and all clients requiring null user storage system access on a separate network, to eliminate the possibility of IP address “spoofing”.

## Related information

[Configuring access restrictions for anonymous users](#)

### Grant null users access to file system shares

You can allow access to your storage system resources by null session clients by assigning a group to be used by null session clients and recording the IP addresses of null session clients to add to the storage system’s list of clients allowed to access data using null sessions.

#### Steps

1. Use the `vserver name-mapping create` command to map the null user to any valid windows user, with an IP qualifier.

The following command maps the null user to user1 with a valid host name google.com:

```
vserver name-mapping create -direction win-unix -position 1 -pattern
"ANONYMOUS LOGON" -replacement user1 -hostname google.com
```

The following command maps the null user to user1 with a valid IP address 10.238.2.54/32:

```
vserver name-mapping create -direction win-unix -position 2 -pattern
"ANONYMOUS LOGON" -replacement user1 -address 10.238.2.54/32
```

2. Use the vserver name-mapping show command to confirm the name mapping.

```
vserver name-mapping show

Vserver: vs1
Direction: win-unix
Position Hostname IP Address/Mask
----- -----
1 - 10.72.40.83/32 Pattern: anonymous logon
 Replacement: user1
```

3. Use the vserver cifs options modify -win-name-for-null-user command to assign Windows membership to the null user.

This option is applicable only when there is a valid name mapping for the null user.

```
vserver cifs options modify -win-name-for-null-user user1
```

4. Use the vserver cifs options show command to confirm the mapping of the null user to the Windows user or group.

```
vserver cifs options show

Vserver :vs1

Map Null User to Windows User of Group: user1
```

## Manage NetBIOS aliases for SMB servers

### Manage NetBIOS aliases for SMB servers overview

NetBIOS aliases are alternative names for your SMB server that SMB clients can use when connecting to the SMB server. Configuring NetBIOS aliases for a SMB server can be useful when you are consolidating data from other file servers to the SMB server and want the SMB server to respond to the original file servers' names.

You can specify a list of NetBIOS aliases when you create the SMB server or at any time after you create the SMB server. You can add or remove NetBIOS aliases from the list at any time. You can connect to the SMB server using any of the names in the NetBIOS alias list.

### Related information

[Displaying information about NetBIOS over TCP connections](#)

## Add a list of NetBIOS aliases to the SMB server

If you want SMB clients to connect to the SMB server by using an alias, you can create a list of NetBIOS aliases, or you can add NetBIOS aliases to an existing list of NetBIOS aliases.

### About this task

- The NetBIOS alias name can be 15 up to characters in length.
- You can configure up to 200 NetBIOS aliases on the SMB server.
- The following characters are not allowed:

@ # \* ( ) = + [ ] | ; : " , < > \ / ?

### Steps

#### 1. Add the NetBIOS aliases:

```
vserver cifs add-netbios-aliases -vserver vserver_name -netbios-aliases
NetBIOS_alias,...
```

```
vserver cifs add-netbios-aliases -vserver vs1 -netbios-aliases
alias_1,alias_2,alias_3
```

- You can specify one or more NetBIOS aliases by using a comma-delimited list.
- The specified NetBIOS aliases are added to the existing list.
- A new list of NetBIOS aliases is created if the list is currently empty.

#### 2. Verify that the NetBIOS aliases were added correctly: `vserver cifs show -vserver vserver_name -display-netbios-aliases`

```
vserver cifs show -vserver vs1 -display-netbios-aliases
```

```
Vserver: vs1

Server Name: CIFS_SERVER
NetBIOS Aliases: ALIAS_1, ALIAS_2, ALIAS_3
```

### Related information

[Removing NetBIOS aliases from the NetBIOS alias list](#)

[Displaying the list of NetBIOS aliases on CIFS servers](#)

### Remove NetBIOS aliases from the NetBIOS alias list

If you do not need specific NetBIOS aliases for a CIFS server, you can remove those NetBIOS aliases from the list. You can also remove all NetBIOS aliases from the list.

### About this task

You can remove more than one NetBIOS alias by using a comma-delimited list. You can remove all of the NetBIOS aliases on a CIFS server by specifying – as the value for the `-netbios-aliases` parameter.

## Steps

1. Perform one of the following actions:

| If you want to remove...               | Enter...                                                                                                           |
|----------------------------------------|--------------------------------------------------------------------------------------------------------------------|
| Specific NetBIOS aliases from the list | vserver cifs remove-netbios-aliases<br>-vserver <u>vserver_name</u> -netbios<br>-aliases <u>NetBIOS_alias</u> ,... |
| All NetBIOS aliases from the list      | vserver cifs remove-netbios-aliases<br>-vserver <u>vserver_name</u> -netbios-aliases<br>-                          |

```
vserver cifs remove-netbios-aliases -vserver vs1 -netbios-aliases alias_1
```

2. Verify that the specified NetBIOS aliases were removed: `vserver cifs show -vserver vserver_name -display-netbios-aliases`

```
vserver cifs show -vserver vs1 -display-netbios-aliases
```

```
Vserver: vs1
```

```
Server Name: CIFS_SERVER
NetBIOS Aliases: ALIAS_2, ALIAS_3
```

## Display the list of NetBIOS aliases on CIFS servers

You can display the list of NetBIOS aliases. This can be useful when you want to determine the list of names over which SMB clients can make connections to the CIFS server.

### Step

1. Perform one of the following actions:

| If you want to display information about...                                 | Enter...                                       |
|-----------------------------------------------------------------------------|------------------------------------------------|
| A CIFS server's NetBIOS aliases                                             | vserver cifs show -display-netbios<br>-aliases |
| The list of NetBIOS aliases as part of the detailed CIFS server information | vserver cifs show -instance                    |

The following example displays information about a CIFS server's NetBIOS aliases:

```
vserver cifs show -display-netbios-aliases
```

```
Vserver: vs1
```

```
 Server Name: CIFS_SERVER
 NetBIOS Aliases: ALIAS_1, ALIAS_2, ALIAS_3
```

The following example displays the list of NetBIOS aliases as part of the detailed CIFS server information:

```
vserver cifs show -instance
```

```
 Vserver: vs1
 CIFS Server NetBIOS Name: CIFS_SERVER
 NetBIOS Domain/Workgroup Name: EXAMPLE
 Fully Qualified Domain Name: EXAMPLE.COM
Default Site Used by LIFs Without Site Membership:
 Authentication Style: domain
 CIFS Server Administrative Status: up
 CIFS Server Description:
 List of NetBIOS Aliases: ALIAS_1, ALIAS_2,
ALIAS_3
```

See the man page for the commands for more information.

## Related information

[Adding a list of NetBIOS aliases to the CIFS server](#)

[Commands for managing CIFS servers](#)

## Determine whether SMB clients are connected using NetBIOS aliases

You can determine whether SMB clients are connected using NetBIOS aliases, and if so, which NetBIOS alias is used to make the connection. This can be useful when troubleshooting connection issues.

### About this task

You must use the `-instance` parameter to display the NetBIOS alias (if any) associated with an SMB connection. If the CIFS server name or an IP address is used to make the SMB connection, the output for the NetBIOS Name field is `-` (hyphen).

### Step

1. Perform the desired action:

| If you want to display NetBIOS information for... | Enter...                                         |
|---------------------------------------------------|--------------------------------------------------|
| SMB connections                                   | <code>vserver cifs session show -instance</code> |

| If you want to display NetBIOS information for... | Enter...                                                              |
|---------------------------------------------------|-----------------------------------------------------------------------|
| Connections using a specified NetBIOS alias:      | vserver cifs session show -instance -netbios-name <i>netbios_name</i> |

The following example displays information about the NetBIOS alias used to make the SMB connection with session ID 1:

```
vserver cifs session show -session-id 1 -instance
```

```

 Node: node1
 Vserver: vs1
 Session ID: 1
 Connection ID: 127834
 Incoming Data LIF IP Address: 10.1.1.25
 Workstation: 10.2.2.50
 Authentication Mechanism: NTLMv2
 Windows User: EXAMPLE\user1
 UNIX User: user1
 Open Shares: 2
 Open Files: 2
 Open Other: 0
 Connected Time: 1d 1h 10m 5s

## Manage miscellaneous SMB server tasks

### Stop or start the CIFS server

You can stop the CIFS server on a SVM, which can be useful when performing tasks while users are not accessing data over SMB shares. You can restart SMB access by starting the CIFS server. By stopping the CIFS server, you can also modify the protocols allowed on the storage virtual machine (SVM).

#### Steps

1. Perform one of the following actions:

| If you want to...     | Enter the command...                                                      |
|-----------------------|---------------------------------------------------------------------------|
| Stop the CIFS server  | vserver cifs stop -vserver<br>vserver_name [-foreground<br>{true false}]  |
| Start the CIFS server | vserver cifs start -vserver<br>vserver_name [-foreground<br>{true false}] |

-foreground specifies whether the command should execute in the foreground or background. If you do not enter this parameter, it is set to true, and the command is executed in the foreground.

- Verify that the CIFS server administrative status is correct by using the vserver cifs show command.

### Example

The following commands start the CIFS server on SVM vs1:

```
cluster1::> vserver cifs start -vserver vs1

cluster1::> vserver cifs show -vserver vs1

 Vserver: vs1
 CIFS Server NetBIOS Name: VS1
 NetBIOS Domain/Workgroup Name: DOMAIN
 Fully Qualified Domain Name: DOMAIN.LOCAL
Default Site Used by LIFs Without Site Membership:
 Authentication Style: domain
 CIFS Server Administrative Status: up
```

### Move CIFS servers to different OUs

The CIFS server create-process uses the default organizational unit (OU) CN=Computers during setup unless you specify a different OU. You can move CIFS servers to different OUs after setup.

### Steps

- On the Windows server, open the **Active Directory Users and Computers** tree.
- Locate the Active Directory object for the storage virtual machine (SVM).
- Right-click the object and select **Move**.
- Select the OU that you want to associate with the SVM

## Results

The SVM object is placed in the selected OU.

### Modify the dynamic DNS domain on the SVM before moving the SMB server

If you want the Active Directory-integrated DNS server to dynamically register the SMB server's DNS records in DNS when you move the SMB server to another domain, you must modify dynamic DNS (DDNS) on the storage virtual machine (SVM) before moving the SMB server.

#### Before you begin

DNS name services must be modified on the SVM to use the DNS domain that contains the service location records for the new domain that will contain the SMB server computer account. If you are using secure DDNS, you must use Active Directory-integrated DNS name servers.

#### About this task

Although DDNS (if configured on the SVM) automatically adds the DNS records for data LIFs to the new domain, the DNS records for the original domain are not automatically deleted from the original DNS server. You must delete them manually.

To complete your DDNS modifications before moving the SMB server, see the following topic:

#### [Configure dynamic DNS services](#)

#### Join a SVM to an Active Directory domain

You can join a storage virtual machine (SVM) to an Active Directory domain without deleting the existing SMB server by modifying the domain using the `vserver cifs modify` command. You can rejoin the current domain or join a new one.

#### Before you begin

- The SVM must already have a DNS configuration.
- The DNS configuration for the SVM must be able to serve the target domain.

The DNS servers must contain the service location records (SRV) for the domain LDAP and domain controller servers.

#### About this task

- The administrative status of the CIFS server must be set to "down" to proceed with Active Directory domain modification.
- If the command completes successfully, the administrative status is automatically set to "up".
- When joining a domain, this command might take several minutes to complete.

#### Steps

1. Join the SVM to the CIFS server domain: `vserver cifs modify -vserver vserver_name -domain domain_name -status-admin down`

For more information, see the man page for the `vserver cifs modify` command. If you need to reconfigure DNS for the new domain, see the man page for the `vserver dns modify` command.

In order to create an Active Directory machine account for the SMB server, you must supply the name and password of a Windows account with sufficient privileges to add computers to the `ou= example ou` container within the `example.com` domain.

Beginning with ONTAP 9.7, your AD administrator can provide you with a URI to a keytab file as an alternative to providing you with a name and password to a privileged Windows account. When you receive the URI, include it in the `-keytab-uri` parameter with the `vserver cifs` commands.

2. Verify that the CIFS server is in the desired Active Directory domain: `vserver cifs show`

### Example

In the following example, the SMB server “CIFSSERVER1” on SVM vs1 joins the `example.com` domain using keytab authentication:

```
cluster1::> vserver cifs modify -vserver vs1 -domain example.com -status
-admin down -keytab-uri http://admin.example.com/ontap1.keytab

cluster1::> vserver cifs show

 Server Status Domain/Workgroup Authentication
Vserver Name Admin Name Style
----- -----
vs1 CIFSSERVER1 up EXAMPLE domain
```

### Display information about NetBIOS over TCP connections

You can display information about NetBIOS over TCP (NBT) connections. This can be useful when troubleshooting NetBIOS-related issues.

#### Step

1. Use the `vserver cifs nbtstat` command to display information about NetBIOS over TCP connections.

NetBIOS name service (NBNS) over IPv6 is not supported.

### Example

The following example shows the NetBIOS name service information displayed for “cluster1”:

```

cluster1::> vserver cifs nbtstat

 Vserver: vs1
 Node: cluster1-01
 Interfaces:
 10.10.10.32
 10.10.10.33
 Servers:
 17.17.1.2 (active)
 NBT Scope:
 []
 NBT Mode:
 [h]
 NBT Name NetBIOS Suffix State Time Left Type
 ----- ----- ----- ----- -----
 CLUSTER_1 00 wins 57
 CLUSTER_1 20 wins 57

 Vserver: vs1
 Node: cluster1-02
 Interfaces:
 10.10.10.35
 Servers:
 17.17.1.2 (active)
 CLUSTER_1 00 wins 58
 CLUSTER_1 20 wins 58
 4 entries were displayed.

```

#### Commands for managing SMB servers

You need to know the commands for creating, displaying, modifying, stopping, starting, and deleting SMB servers. There are also commands to reset and rediscover servers, change or reset machine account passwords, schedule changes for machine account passwords, and add or remove NetBIOS aliases.

| If you want to...                       | Use this command... |
|-----------------------------------------|---------------------|
| Create an SMB server                    | vserver cifs create |
| Display information about an SMB server | vserver cifs show   |
| Modify an SMB server                    | vserver cifs modify |
| Move an SMB server to another domain    | vserver cifs modify |

|                                                                          |                                                      |
|--------------------------------------------------------------------------|------------------------------------------------------|
| Stop an SMB server                                                       | vserver cifs stop                                    |
| Start an SMB server                                                      | vserver cifs start                                   |
| Delete an SMB server                                                     | vserver cifs delete                                  |
| Reset and rediscover servers for the SMB server                          | vserver cifs domain discovered-servers reset-servers |
| Change the SMB server's machine account password                         | vserver cifs domain password change                  |
| Reset the SMB server's machine account password                          | vserver cifs domain password change                  |
| Schedule automatic password changes for the SMB server's machine account | vserver cifs domain password schedule modify         |
| Add NetBIOS aliases for the SMB server                                   | vserver cifs add-netbios-aliases                     |
| Remove NetBIOS aliases for the SMB server                                | vserver cifs remove-netbios-aliases                  |

See the man page for each command for more information.

## Enable the NetBios name service

Beginning with ONTAP 9, the NetBios name service (NBNS, sometimes called Windows Internet Name Service or WINS) is disabled by default. Previously, CIFS-enabled storage virtual machines (SVMs) sent name registration broadcasts regardless of whether WINS was enabled on a network. To limit such broadcasts to configurations where NBNS is required, you must enable NBNS explicitly for new CIFS servers.

### Before you begin

- If you are already using NBNS and you upgrade to ONTAP 9, it is not necessary to complete this task. NBNS will continue to work as before.
- NBNS is enabled over UDP (port 137).
- NBNS over IPv6 is not supported.

### Steps

1. Set the privilege level to advanced.

```
set -privilege advanced
```

2. Enable NBNS on a CIFS server.

```
vserver cifs options modify -vserver <vserver name> -is-nbns-enabled true
```

3. Return to the admin privilege level.

```
set -privilege admin
```

## Use IPv6 for SMB access and SMB services

### Requirements for using IPv6

Before you can use IPv6 on your SMB server, you need to know which versions of ONTAP and SMB support it and what the license requirements are.

### ONTAP license requirements

No special license is required for IPv6 when SMB is licensed.

### SMB protocol version requirements

- For SVMs, ONTAP supports IPv6 on all versions of the SMB protocol.

NetBIOS name service (NBNS) over IPv6 is not supported.

### Support for IPv6 with SMB access and CIFS services

If you want to use IPv6 on your CIFS server, you need to be aware of how ONTAP supports IPv6 for SMB access and network communication for CIFS services.

### Windows client and server support

ONTAP provides support for Windows servers and clients that support IPv6. The following describes Microsoft Windows client and server IPv6 support:

- Windows XP and Windows 2003 support IPv6 for SMB file sharing.

These versions provide limited support for IPv6.

- Windows 7, Windows 8, Windows Server 2008, Windows Server 2012 and later support IPv6 for both SMB file sharing and Active Directory services, including DNS, LDAP, CLDAP, and Kerberos services.

If IPv6 addresses are configured, Windows 7 and Windows Server 2008 and later releases use IPv6 by default for Active Directory services. Both NTLM and Kerberos authentication over IPv6 connections are supported.

All Windows clients supported by ONTAP can connect to SMB shares by using IPv6 addresses.

For the latest information about which Windows clients ONTAP supports, see the Interoperability Matrix.

## Interoperability Matrix

NT domains are not supported for IPv6.

## Additional CIFS services support

In addition to IPv6 support for SMB file shares and Active Directory services, ONTAP provides IPv6 support for the following:

- Client-side services, including offline folders, roaming profiles, folder redirection, and Previous Versions
- Server-side services, including Dynamic home directories (Home Directory feature), symlinks and Widelinks, BranchCache, ODX copy offload, automatic node referrals, and Previous Versions
- File access management services, including the use of Windows local users and groups for access control and rights management, setting file permissions and audit policies using the CLI, security tracing, file locks management, and monitoring SMB activity
- NAS multiprotocol auditing
- FPolicy
- Continuously available shares, Witness protocol, and Remote VSS (used with Hyper-V over SMB configurations)

## Name service and authentication service support

Communication with the following name services are supported with IPv6:

- Domain controllers
- DNS servers
- LDAP servers
- KDC servers
- NIS servers

## How CIFS servers use IPv6 to connect to external servers

To create a configuration that meets your requirements, you must be aware of how CIFS servers use IPv6 when making connections to external servers.

- Source address selection

If an attempt is made to connect to an external server, the source address selected must be of the same type as the destination address. For example, if connecting to an IPv6 address, the storage virtual machine (SVM) hosting the CIFS server must have a data LIF or management LIF that has an IPv6 address to use as the source address. Similarly, if connecting to an IPv4 address, the SVM must have a data LIF or management LIF that has an IPv4 address to use as the source address.

- For servers dynamically discovered using DNS, server discovery is performed as follows:
  - If IPv6 is disabled on the cluster, only IPv4 servers addresses are discovered.
  - If IPv6 is enabled on the cluster, both IPv4 and IPv6 server addresses are discovered. Either type might be used depending upon the suitability of the server to which the address belongs and the

availability of IPv6 or IPv4 data or management LIFs.

Dynamic server discovery is used for discovering Domain Controllers and their associated services, such as LSA, NETLOGON, Kerberos, and LDAP.

- DNS server connectivity

Whether the SVM uses IPv6 when connecting to a DNS server depends on the DNS name services configuration. If DNS services are configured to use IPv6 addresses, connections are made by using IPv6. If desired, the DNS name services configuration can use IPv4 addresses so that connections to DNS servers continue to use IPv4 addresses. Combinations of IPv4 and IPv6 addresses can be specified when configuring DNS name services.

- LDAP server connectivity

Whether the SVM uses IPv6 when connecting to an LDAP server depends on the LDAP client configuration. If the LDAP client is configured to use IPv6 addresses, connections are made by using IPv6. If desired, the LDAP client configuration can use IPv4 addresses so that connections to LDAP servers continue to use IPv4 addresses. Combinations of IPv4 and IPv6 addresses can be specified when configuring the LDAP client configuration.

The LDAP client configuration is used when configuring LDAP for UNIX user, group, and netgroup name services.

- NIS server connectivity

Whether the SVM uses IPv6 when connecting to a NIS server depends on the NIS name services configuration. If NIS services are configured to use IPv6 addresses, connections are made by using IPv6. If desired, the NIS name services configuration can use IPv4 addresses so that connections to NIS servers continue to use IPv4 addresses. Combinations of IPv4 and IPv6 addresses can be specified when configuring NIS name services.

NIS name services are used for storing and managing UNIX user, group, netgroup, and host name objects.

## Related information

[Enabling IPv6 for SMB \(cluster administrators only\)](#)

[Monitoring and displaying information about IPv6 SMB sessions](#)

[Enable IPv6 for SMB \(cluster administrators only\)](#)

IPv6 networks are not enabled during cluster setup. A cluster administrator must enable IPv6 after cluster setup is complete to use IPv6 for SMB. When the cluster administrator enables IPv6, it is enabled for the entire cluster.

## Step

1. Enable IPv6: `network options ipv6 modify -enabled true`

For more information about enabling IPv6 on the cluster and configuring IPv6 LIFs, see the *Network Management Guide*.

IPv6 is enabled. IPv6 data LIFs for SMB access can be configured.

## Related information

[Monitoring and displaying information about IPv6 SMB sessions](#)

## Network management

### Disable IPv6 for SMB

Even though IPv6 is enabled on the cluster using a network option, you cannot disable IPv6 for SMB by using the same command. Instead, ONTAP disables IPv6 when the cluster administrator disables the last IPv6-enabled interface on the cluster. You should communicate with the cluster administrator about management of your IPv6 enabled interfaces.

For more information about disabling IPv6 on the cluster, see the *Network Management Guide*.

## Related information

[Network management](#)

### Monitor and display information about IPv6 SMB sessions

You can monitor and display information about SMB sessions that are connected using IPv6 networks. This information is useful in determining which clients are connecting using IPv6 as well as other useful information about IPv6 SMB sessions.

#### Step

1. Perform the desired action:

| If you want to determine whether...                                      | Enter the command...                                                                                                                                                           |
|--------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| SMB sessions to a storage virtual machine (SVM) are connected using IPv6 | <code>vserver cifs session show -vserver<br/>vserver_name -instance</code>                                                                                                     |
| IPv6 is used for SMB sessions through a specified LIF address            | <code>vserver cifs session show -vserver<br/>vserver_name -lif-address<br/><i>LIF_IP_address</i> -instance</code><br><br><i>LIF_IP_address</i> is the data LIF's IPv6 address. |

## Set up file access using SMB

### Configure security styles

#### How security styles affect data access

#### What the security styles and their effects are

There are four different security styles: UNIX, NTFS, mixed, and unified. Each security style has a different effect on how permissions are handled for data. You must understand the different effects to ensure that you select the appropriate security style for your

purposes.

It is important to understand that security styles do not determine what client types can or cannot access data. Security styles only determine the type of permissions ONTAP uses to control data access and what client type can modify these permissions.

For example, if a volume uses UNIX security style, SMB clients can still access data (provided that they properly authenticate and authorize) due to the multiprotocol nature of ONTAP. However, ONTAP uses UNIX permissions that only UNIX clients can modify using native tools.

| Security style                                                            | Clients that can modify permissions | Permissions that clients can use | Resulting effective security style | Clients that can access files |
|---------------------------------------------------------------------------|-------------------------------------|----------------------------------|------------------------------------|-------------------------------|
| UNIX                                                                      | NFS                                 | NFSv3 mode bits                  | UNIX                               | NFS and SMB                   |
|                                                                           |                                     | NFSv4.x ACLs                     | UNIX                               |                               |
| NTFS                                                                      | SMB                                 | NTFS ACLs                        | NTFS                               |                               |
| Mixed                                                                     | NFS or SMB                          | NFSv3 mode bits                  | UNIX                               |                               |
|                                                                           |                                     | NFSv4.x ACLs                     | UNIX                               |                               |
| NTFS ACLs                                                                 | NTFS                                | Unified                          | NFS or SMB                         |                               |
| NFSv3 mode bits                                                           | UNIX                                |                                  |                                    |                               |
| NFSv4.1 ACLs                                                              | UNIX                                | NTFS ACLs                        | NTFS                               |                               |
| Unified<br>(For infinite volumes only, in ONTAP 9.4 and earlier releases) | NFS or SMB                          | NFSv3 mode bits                  | Unix                               | NTFS ACLs                     |
|                                                                           |                                     | NFSv4.1 ACLs                     |                                    |                               |

FlexVol volumes support UNIX, NTFS, and mixed security styles. When the security style is mixed or unified, the effective permissions depend on the client type that last modified the permissions because users set the security style on an individual basis. If the last client that modified permissions was an NFSv3 client, the permissions are UNIX NFSv3 mode bits. If the last client was an NFSv4 client, the permissions are NFSv4 ACLs. If the last client was an SMB client, the permissions are Windows NTFS ACLs.

The unified security style is only available with infinite volumes, which are no longer supported in ONTAP 9.5 and later releases. For more information, see [FlexGroup volumes management overview](#).

Beginning with ONTAP 9.2, the `show-effective-permissions` parameter to the `vserver security file-directory` command enables you to display effective permissions granted to a Windows or UNIX user on the specified file or folder path. In addition, the optional parameter `-share-name` enables you to display the effective share permission.

ONTAP initially sets some default file permissions. By default, the effective security style on all data in UNIX, mixed, and unified security style volumes is UNIX and the effective permissions type is UNIX mode bits (0755 unless specified otherwise) until configured by a client as allowed by the default security style. By default, the effective security style on all data in NTFS security style volumes is NTFS and has an ACL allowing full control to everyone.

## Where and when to set security styles

Security styles can be set on FlexVol volumes (both root or data volumes) and qtrees. Security styles can be set manually at the time of creation, inherited automatically, or changed at a later time.

### Decide which security style to use on SVMs

To help you decide which security style to use on a volume, you should consider two factors. The primary factor is the type of administrator that manages the file system. The secondary factor is the type of user or service that accesses the data on the volume.

When you configure the security style on a volume, you should consider the needs of your environment to ensure that you select the best security style and avoid issues with managing permissions. The following considerations can help you decide:

| Security style | Choose if...                                                                                                                                                                                                                                |
|----------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

| NTFS           | <ul style="list-style-type: none"><li>The file system is managed by a Windows administrator.</li><li>The majority of users are SMB clients.</li><li>An application accessing the data uses a Windows user as the service account.</li></ul> |
| Mixed          | The file system is managed by both UNIX and Windows administrators and users consist of both NFS and SMB clients.                                                                                                                           |

### How security style inheritance works

If you do not specify the security style when creating a new FlexVol volume or a qtree, it inherits its security style in different ways.

Security styles are inherited in the following manner:

- A FlexVol volume inherits the security style of the root volume of its containing SVM.

- A qtree inherits the security style of its containing FlexVol volume.
- A file or directory inherits the security style of its containing FlexVol volume or qtree.

## How ONTAP preserves UNIX permissions

When files in a FlexVol volume that currently have UNIX permissions are edited and saved by Windows applications, ONTAP can preserve the UNIX permissions.

When applications on Windows clients edit and save files, they read the security properties of the file, create a new temporary file, apply those properties to the temporary file, and then give the temporary file the original file name.

When Windows clients perform a query for the security properties, they receive a constructed ACL that exactly represents the UNIX permissions. The sole purpose of this constructed ACL is to preserve the file's UNIX permissions as files are updated by Windows applications to ensure that the resulting files have the same UNIX permissions. ONTAP does not set any NTFS ACLs using the constructed ACL.

## Manage UNIX permissions using the Windows Security tab

If you want to manipulate UNIX permissions of files or folders in mixed security-style volumes or qtrees on SVMs, you can use the Security tab on Windows clients. Alternatively, you can use applications that can query and set Windows ACLs.

- Modifying UNIX permissions

You can use the Windows Security tab to view and change UNIX permissions for a mixed security-style volume or qtree. If you use the main Windows Security tab to change UNIX permissions, you must first remove the existing ACE you want to edit (this sets the mode bits to 0) before you make your changes. Alternatively, you can use the Advanced editor to change permissions.

If mode permissions are used, you can directly change the mode permissions for the listed UID, GID, and others (everyone else with an account on the computer). For example, if the displayed UID has r-x permissions, you can change the UID permissions to rwx.

- Changing UNIX permissions to NTFS permissions

You can use the Windows Security tab to replace UNIX security objects with Windows security objects on a mixed security-style volume or qtree where the files and folders have a UNIX effective security style.

You must first remove all listed UNIX permission entries before you can replace them with the desired Windows User and Group objects. You can then configure NTFS-based ACLs on the Windows User and Group objects. By removing all UNIX security objects and adding only Windows Users and Groups to a file or folder in a mixed security-style volume or qtree, you change the effective security style on the file or folder from UNIX to NTFS.

When changing permissions on a folder, the default Windows behavior is to propagate these changes to all subfolders and files. Therefore, you must change the propagation choice to the desired setting if you do not want to propagate a change in security style to all child folders, subfolders, and files.

## Configure security styles on SVM root volumes

You configure the storage virtual machine (SVM) root volume security style to determine

the type of permissions used for data on the root volume of the SVM.

### Steps

1. Use the `vserver create` command with the `-rootvolume-security-style` parameter to define the security style.

The possible options for the root volume security style are `unix`, `ntfs`, or `mixed`.

2. Display and verify the configuration, including the root volume security style of the SVM you created:

```
vserver show -vserver vserver_name
```

### Configure security styles on FlexVol volumes

You configure the FlexVol volume security style to determine the type of permissions used for data on FlexVol volumes of the storage virtual machine (SVM).

### Steps

1. Perform one of the following actions:

| If the FlexVol volume... | Use the command...                                                                                               |
|--------------------------|------------------------------------------------------------------------------------------------------------------|
| Does not yet exist       | <code>volume create</code> and include the <code>-security-style</code> parameter to specify the security style. |
| Already exists           | <code>volume modify</code> and include the <code>-security-style</code> parameter to specify the security style. |

The possible options for the FlexVol volume security style are `unix`, `ntfs`, or `mixed`.

If you do not specify a security style when creating a FlexVol volume, the volume inherits the security style of the root volume.

For more information about the `volume create` or `volume modify` commands, see [Logical storage management](#).

2. To display the configuration, including the security style of the FlexVol volume you created, enter the following command:

```
volume show -volume volume_name -instance
```

### Configure security styles on qtrees

You configure the qtree volume security style to determine the type of permissions used for data on qtrees.

### Steps

1. Perform one of the following actions:

| If the qtree...    | Use the command...                                                                           |
|--------------------|----------------------------------------------------------------------------------------------|
| Does not exist yet | volume qtree create and include the -security-style parameter to specify the security style. |
| Already exists     | volume qtree modify and include the -security-style parameter to specify the security style. |

The possible options for the qtree security style are unix, ntfs, or mixed.

If you do not specify a security style when creating a qtree, the default security style is mixed.

For more information about the volume qtree create or volume qtree modify commands, see [Logical storage management](#).

2. To display the configuration, including the security style of the qtree you created, enter the following command: volume qtree show -qtree qtree\_name -instance

## Create and manage data volumes in NAS namespaces

### Create and manage data volumes in NAS namespaces overview

To manage file access in a NAS environment, you must manage data volumes and junction points on your storage virtual machine (SVM). This includes planning your namespace architecture, creating volumes with or without junction points, mounting or unmounting volumes, and displaying information about data volumes and NFS server or CIFS server namespaces.

#### Create data volumes with specified junction points

You can specify the junction point when you create a data volume. The resultant volume is automatically mounted at the junction point and is immediately available to configure for NAS access.

#### Before you begin

The aggregate in which you want to create the volume must already exist.

 The following characters cannot be used in the junction path: \* # " > < | ? \

In addition, the junction path length cannot be more than 255 characters.

#### Steps

1. Create the volume with a junction point: volume create -vserver vserver\_name -volume volume\_name -aggregate aggregate\_name -size {integer[KB|MB|GB|TB|PB]} -security-style {ntfs|unix|mixed} -junction-path junction\_path

The junction path must start with the root (/) and can contain both directories and junctioned volumes. The junction path does not need to contain the name of the volume. Junction paths are independent of the

volume name.

Specifying a volume security style is optional. If you do not specify a security style, ONTAP creates the volume with the same security style that is applied to the root volume of the storage virtual machine (SVM). However, the root volume's security style might not be the security style you want applied to the data volume you create. The recommendation is to specify the security style when you create the volume to minimize difficult-to-troubleshoot file-access issues.

The junction path is case insensitive; /ENG is the same as /eng. If you create a CIFS share, Windows treats the junction path as if it is case sensitive. For example, if the junction is /ENG, the path of a CIFS share must start with /ENG, not /eng.

There are many optional parameters that you can use to customize a data volume. To learn more about them, see the man pages for the `volume create` command.

2. Verify that the volume was created with the desired junction point: `volume show -vserver vserver_name -volume volume_name -junction`

### Example

The following example creates a volume named "home4" located on SVM vs1 that has a junction path /eng/home:

```
cluster1::> volume create -vserver vs1 -volume home4 -aggregate aggr1
-size 1g -junction-path /eng/home
[Job 1642] Job succeeded: Successful

cluster1::> volume show -vserver vs1 -volume home4 -junction
 Junction Junction
Vserver Volume Active Junction Path Path Source
----- -----
vs1 home4 true /eng/home RW_volume
```

### Create data volumes without specifying junction points

You can create a data volume without specifying a junction point. The resultant volume is not automatically mounted, and is not available to configure for NAS access. You must mount the volume before you can configure SMB shares or NFS exports for that volume.

#### Before you begin

The aggregate in which you want to create the volume must already exist.

#### Steps

1. Create the volume without a junction point by using the following command: `volume create -vserver vserver_name -volume volume_name -aggregate aggregate_name -size {integer[KB|MB|GB|TB|PB]} -security-style {ntfs|unix|mixed}`

Specifying a volume security style is optional. If you do not specify a security style, ONTAP creates the volume with the same security style that is applied to the root volume of the storage virtual machine (SVM). However, the root volume's security style might not be the security style you want applied to the data volume. The recommendation is to specify the security style when you create the volume to minimize

difficult-to-troubleshoot file-access issues.

There are many optional parameters that you can use to customize a data volume. To learn more about them, see the man pages for the `volume create` command.

- Verify that the volume was created without a junction point: `volume show -vserver vserver_name -volume volume_name -junction`

### Example

The following example creates a volume named “sales” located on SVM vs1 that is not mounted at a junction point:

```
cluster1::> volume create -vserver vs1 -volume sales -aggregate aggr3
-size 20GB
[Job 3406] Job succeeded: Successful

cluster1::> volume show -vserver vs1 -junction

Vserver	Volume	Active	Junction Path	Junction Path Source
vs1	data	true	/data	RW_volume
vs1	home4	true	/eng/home	RW_volume
vs1	vs1_root	-	/	-
vs1	sales	-	-	-

```

### Mount or unmount existing volumes in the NAS namespace

A volume must be mounted on the NAS namespace before you can configure NAS client access to data contained in the storage virtual machine (SVM) volumes. You can mount a volume to a junction point if it is not currently mounted. You can also unmount volumes.

#### About this task

If you unmount and offline a volume, all data within the junction point, including data in volumes with junction points contained within the unmounted volume’s namespace, are inaccessible to NAS clients.

To discontinue NAS client access to a volume, it is not sufficient to simply unmount the volume. You must offline the volume, or take other steps to ensure that client-side file handle caches are invalidated. For more information, see the following Knowledge Base article:[https://kb.netapp.com/Advice\\_and\\_Troubleshooting/Data\\_Storage\\_Software/ONTAP\\_OS/NFSv3\\_clients\\_still\\_have\\_access\\_to\\_a\\_volume\\_after\\_being\\_removed\\_from\\_the\\_namespace\\_in\\_ONTAP\[NFSv3 clients still have access to a volume after being removed from the namespace in ONTAP\]](https://kb.netapp.com/Advice_and_Troubleshooting/Data_Storage_Software/ONTAP_OS/NFSv3_clients_still_have_access_to_a_volume_after_being_removed_from_the_namespace_in_ONTAP[NFSv3 clients still have access to a volume after being removed from the namespace in ONTAP])

When you unmount and offline a volume, data within the volume is not lost. Additionally, existing volume export policies and SMB shares created on the volume or on directories and junction points within the unmounted volume are retained. If you remount the unmounted volume, NAS clients can access the data contained within the volume using existing export policies and SMB shares.

#### Steps

1. Perform the desired action:

| If you want to... | Enter the commands...                                                                                                                    |
|-------------------|------------------------------------------------------------------------------------------------------------------------------------------|
| Mount a volume    | volume mount -vserver <i>svm_name</i> -volume <i>volume_name</i> -junction-path <i>junction_path</i>                                     |
| Unmount a volume  | volume unmount -vserver <i>svm_name</i> -volume <i>volume_name</i> volume offline<br>-vserver <i>svm_name</i> -volume <i>volume_name</i> |

2. Verify that the volume is in the desired mount state: `volume show -vserver vserver_name -volume volume_name -fields state,junction-path,junction-active`

### Examples

The following example mounts a volume named “sales” located on SVM vs1 to the junction point /sales:

```
cluster1::> volume mount -vserver vs1 -volume sales -junction-path /sales

cluster1::> volume show -vserver vs1 state,junction-path,junction-active

vserver volume state junction-path junction-active
----- ----- -----
vs1 data online /data true
vs1 home4 online /eng/home true
vs1 sales online /sales true
```

The following example unmounts and offline a volume named “data” located on SVM vs1:

```
cluster1::> volume unmount -vserver vs1 -volume data
cluster1::> volume offline -vserver vs1 -volume data

cluster1::> volume show -vserver vs1 -fields state,junction-path,junction-
active

vserver volume state junction-path junction-active
----- ----- -----
vs1 data offline - -
vs1 home4 online /eng/home true
vs1 sales online /sales true
```

### Display volume mount and junction point information

You can display information about mounted volumes for storage virtual machines (SVMs)

and the junction points to which the volumes are mounted. You can also determine which volumes are not mounted to a junction point. You can use this information to understand and manage your SVM namespace.

## Steps

1. Perform the desired action:

| If you want to display...                                           | Enter the command...                                                                                                                                                                                                                                        |
|---------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Summary information about mounted and unmounted volumes on the SVM  | volume show -vserver vserver_name -junction                                                                                                                                                                                                                 |
| Detailed information about mounted and unmounted volumes on the SVM | volume show -vserver vserver_name -volume volume_name -instance                                                                                                                                                                                             |
| Specific information about mounted and unmounted volumes on the SVM | a. If necessary, you can display valid fields for the -fields parameter by using the following command: volume show -fields ?<br>b. Display the desired information by using the -fields parameter: volume show -vserver vserver_name -fields fieldname,... |

## Examples

The following example displays a summary of mounted and unmounted volumes on SVM vs1:

```
cluster1::> volume show -vserver vs1 -junction
 Junction Junction
Vserver Volume Active Junction Path Path Source
----- -----
vs1 data true /data RW_volume
vs1 home4 true /eng/home RW_volume
vs1 vs1_root - / -
vs1 sales true /sales RW_volume
```

The following example displays information about specified fields for volumes located on SVM vs2:

```

cluster1::> volume show -vserver vs2 -fields
vserver,volume,aggregate,size,state,type,security-style,junction-
path,junction-parent,node
vserver volume aggregate size state type security-style junction-path
junction-parent node

----- ----- ----- ----- ----- -----
vs2 data1 aggr3 2GB online RW unix -
node3
vs2 data2 aggr3 1GB online RW ntfs /data2

```

## Configure name mappings

### Configure name mappings overview

ONTAP uses name mapping to map CIFS identities to UNIX identities, Kerberos identities to UNIX identities, and UNIX identities to CIFS identities. It needs this information to obtain user credentials and provide proper file access regardless of whether they are connecting from an NFS client or a CIFS client.

There are two exceptions where you do not have to use name mapping:

- You configure a pure UNIX environment and do not plan to use CIFS access or NTFS security style on volumes.
- You configure the default user to be used instead.

In this scenario, name mapping is not required because instead of mapping every individual client credential all client credentials are mapped to the same default user.

Note that you can use name mapping only for users, not for groups.

However, you can map a group of individual users to a specific user. For example, you can map all AD users that start or end with the word SALES to a specific UNIX user and to the user's UID.

## How name mapping works

When ONTAP has to map credentials for a user, it first checks the local name mapping database and LDAP server for an existing mapping. Whether it checks one or both and in which order is determined by the name service configuration of the SVM.

- For Windows to UNIX mapping

If no mapping is found, ONTAP checks whether the lowercase Windows user name is a valid user name in the UNIX domain. If this does not work, it uses the default UNIX user provided that it is configured. If the default UNIX user is not configured and ONTAP cannot obtain a mapping this way either, mapping fails and an error is returned.

- For UNIX to Windows mapping

If no mapping is found, ONTAP tries to find a Windows account that matches the UNIX name in the SMB domain. If this does not work, it uses the default SMB user, provided that it is configured. If the default CIFS user is not configured and ONTAP cannot obtain a mapping this way either, mapping fails and an error is returned.

Machine accounts are mapped to the specified default UNIX user by default. If no default UNIX user is specified, machine account mappings fail.

- Beginning with ONTAP 9.5, you can map machine accounts to users other than the default UNIX user.
- In ONTAP 9.4 and earlier, you cannot map machine accounts to other users.

Even if name mappings for machine accounts are defined, the mappings are ignored.

## Multidomain searches for UNIX user to Windows user name mappings

ONTAP supports multidomain searches when mapping UNIX users to Windows users. All discovered trusted domains are searched for matches to the replacement pattern until a matching result is returned. Alternatively, you can configure a list of preferred trusted domains, which is used instead of the discovered trusted domain list and is searched in order until a matching result is returned.

## How domain trusts affect UNIX user to Windows user name mapping searches

To understand how multidomain user name mapping works, you must understand how domain trusts work with ONTAP. Active Directory trust relationships with the CIFS server's home domain can be a bidirectional trust or can be one of two types of unidirectional trusts, either an inbound trust or an outbound trust. The home domain is the domain to which the CIFS server on the SVM belongs.

- *Bidirectional trust*

With bidirectional trusts, both domains trust each other. If the CIFS server's home domain has a bidirectional trust with another domain, the home domain can authenticate and authorize a user belonging to the trusted domain and vice versa.

UNIX user to Windows user name mapping searches can be performed only on domains with bidirectional trusts between the home domain and the other domain.

- *Outbound trust*

With an outbound trust, the home domain trusts the other domain. In this case, the home domain can authenticate and authorize a user belonging to the outbound trusted domain.

A domain with an outbound trust with the home domain is *not* searched when performing UNIX user to Windows user name mapping searches.

- *Inbound trust*

With an inbound trust, the other domain trusts the CIFS server's home domain. In this case, the home domain cannot authenticate or authorize a user belonging to the inbound trusted domain.

A domain with an inbound trust with the home domain is *not* searched when performing UNIX user to Windows user name mapping searches.

### How wildcards (\*) are used to configure multidomain searches for name mapping

Multidomain name mapping searches are facilitated by the use of wildcards in the domain section of the Windows user name. The following table illustrates how to use wildcards in the domain part of a name mapping entry to enable multidomain searches:

| Pattern | Replacement      | Result                                                                                                                                                                                                                                                                                                                                                                                                                   |
|---------|------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| root    | *\\administrator | The UNIX user "root" is mapped to the user named "administrator". All trusted domains are searched in order until the first matching user named "administrator" is found.                                                                                                                                                                                                                                                |
| *       | *\\*             | Valid UNIX users are mapped to the corresponding Windows users. All trusted domains are searched in order until the first matching user with that name is found. <div style="text-align: right; margin-top: 10px;">  The pattern *\\* is only valid for name mapping from UNIX to Windows, not the other way around.         </div> |

### How multidomain name searches are performed

You can choose one of two methods for determining the list of trusted domains used for multidomain name searches:

- Use the automatically discovered bidirectional trust list compiled by ONTAP
- Use the preferred trusted domain list that you compile

If a UNIX user is mapped to a Windows user with a wildcard used for the domain section of the user name, the Windows user is looked up in all the trusted domains as follows:

- If a preferred trusted-domain list is configured, the mapped Windows user is looked up in this search list only, in order.
- If a preferred list of trusted domains is not configured, then the Windows user is looked up in all the bidirectional trusted domains of the home domain.
- If there are no bidirectionally trusted domains for the home domain, the user is looked up in the home domain.

If a UNIX user is mapped to a Windows user without a domain section in the user name, the Windows user is looked up in the home domain.

#### Name mapping conversion rules

An ONTAP system keeps a set of conversion rules for each SVM. Each rule consists of two pieces: a *pattern* and a *replacement*. Conversions start at the beginning of the appropriate list and perform a substitution based on the first matching rule. The pattern is a UNIX-style regular expression. The replacement is a string containing escape sequences representing subexpressions from the pattern, as in the UNIX sed program.

#### Create a name mapping

You can use the `vserver name-mapping create` command to create a name mapping. You use name mappings to enable Windows users to access UNIX security style volumes and the reverse.

#### About this task

For each SVM, ONTAP supports up to 12,500 name mappings for each direction.

#### Step

1. Create a name mapping: `vserver name-mapping create -vserver vserver_name -direction {krb-unix|win-unix|unix-win} -position integer -pattern text -replacement text`

The `-pattern` and `-replacement` statements can be formulated as regular expressions. You can also use the `-replacement` statement to explicitly deny a mapping to the user by using the null replacement string " " (the space character). See the `vserver name-mapping create` man page for details.

When Windows-to-UNIX mappings are created, any SMB clients that have open connections to the ONTAP system at the time the new mappings are created must log out and log back in to see the new mappings.

#### Examples

The following command creates a name mapping on the SVM named vs1. The mapping is a mapping from UNIX to Windows at position 1 in the priority list. The mapping maps the UNIX user johnd to the Windows user ENG\JohnDoe.

```
vs1::> vserver name-mapping create -vserver vs1 -direction unix-win
-position 1 -pattern johnd
-replacement "ENG\\JohnDoe"
```

The following command creates another name mapping on the SVM named vs1. The mapping is a mapping from Windows to UNIX at position 1 in the priority list. Here the pattern and replacement include regular expressions. The mapping maps every CIFS user in the domain ENG to users in the LDAP domain associated with the SVM.

```
vs1::> vserver name-mapping create -vserver vs1 -direction win-unix
-position 1 -pattern "ENG\\(.+)"
-replacement "\1"
```

The following command creates another name mapping on the SVM named vs1. Here the pattern includes “\$” as an element in the Windows user name that must be escaped. The mapping maps the windows user ENG\john\$ops to UNIX user john\_ops.

```
vs1::> vserver name-mapping create -direction win-unix -position 1
-pattern ENG\\john\\$ops
-replacement john_ops
```

#### Configure the default user

You can configure a default user to use if all other mapping attempts fail for a user, or if you do not want to map individual users between UNIX and Windows. Alternatively, if you want authentication of non-mapped users to fail, you should not configure a default user.

#### About this task

For CIFS authentication, if you do not want to map each Windows user to an individual UNIX user, you can instead specify a default UNIX user.

For NFS authentication, if you do not want to map each UNIX user to an individual Windows user, you can instead specify a default Windows user.

#### Steps

1. Perform one of the following actions:

| If you want to...                  | Enter the following command...                                   |
|------------------------------------|------------------------------------------------------------------|
| Configure the default UNIX user    | vserver cifs options modify -default -unix-user <i>user_name</i> |
| Configure the default Windows user | vserver nfs modify -default-win-user <i>user_name</i>            |

## Commands for managing name mappings

There are specific ONTAP commands for managing name mappings.

| If you want to...                                                                                                                                                   | Use this command...                                                                                                  |
|---------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------|
| Create a name mapping                                                                                                                                               | vserver name-mapping create                                                                                          |
| Insert a name mapping at a specific position                                                                                                                        | vserver name-mapping insert                                                                                          |
| Display name mappings                                                                                                                                               | vserver name-mapping show                                                                                            |
| Exchange the position of two name mappings                                                                                                                          | vserver name-mapping swap                                                                                            |
|  A swap is not allowed when name-mapping is configured with an ip-qualifier entry. |                                                                                                                      |
| Modify a name mapping                                                                                                                                               | vserver name-mapping modify                                                                                          |
| Delete a name mapping                                                                                                                                               | vserver name-mapping delete                                                                                          |
| Validate the correct name mapping                                                                                                                                   | vserver security file-directory show-effective-permissions -vserver vs1 -win-user-name user1 -path / -share-name sh1 |

See the man page for each command for more information.

## Configure multidomain name-mapping searches

### Enable or disable multidomain name mapping searches

With multidomain name mapping searches, you can use a wild card (\*) in the domain portion of a Windows name when configuring UNIX user to Windows user name mapping. Using a wild card (\*) in the domain portion of the name enables ONTAP to search all domains that have a bidirectional trust with the domain that contains the CIFS server's computer account.

### About this task

As an alternative to searching all bidirectionally trusted domains, you can configure a list of preferred trusted domains. When a list of preferred trusted domains is configured, ONTAP uses the preferred trusted domain list instead of the discovered bidirectionally trusted domains to perform multidomain name mapping searches.

- Multidomain name mapping searches are enabled by default.
- This option is available at the advanced privilege level.

### Steps

1. Set the privilege level to advanced: `set -privilege advanced`

2. Perform one of the following actions:

| If you want multidomain name mapping searches to be... | Enter the command...                                                                                         |
|--------------------------------------------------------|--------------------------------------------------------------------------------------------------------------|
| Enabled                                                | <code>vserver cifs options modify -vserver vserver_name -is-trusted-domain-enum -search-enabled true</code>  |
| Disabled                                               | <code>vserver cifs options modify -vserver vserver_name -is-trusted-domain-enum -search-enabled false</code> |

3. Return to the admin privilege level: `set -privilege admin`

#### Reset and rediscover trusted domains

You can force the rediscovery of all the trusted domains. This can be useful when the trusted domain servers are not responding appropriately or the trust relationships have changed. Only domains with a bidirectional trust with the home domain, which is the domain containing the CIFS server's computer account, are discovered.

#### Step

1. Reset and rediscover trusted domains by using the `vserver cifs domain trusts rediscover` command.

```
vserver cifs domain trusts rediscover -vserver vs1
```

#### Related information

[Displaying information about discovered trusted domains](#)

#### Display information about discovered trusted domains

You can display information about the discovered trusted domains for the CIFS server's home domain, which is the domain containing the CIFS server's computer account. This can be useful when you want to know which trusted domains are discovered and how they are ordered within the discovered trusted-domain list.

#### About this task

Only the domains with bidirectional trusts with the home domain are discovered. Since the home domain's domain controller (DC) returns the list of trusted domains in an order determined by the DC, the order of the domains within the list cannot be predicted. By displaying the list of trusted domains, you can determine the search order for multidomain name mapping searches.

The displayed trusted domain information is grouped by node and storage virtual machine (SVM).

## Step

1. Display information about discovered trusted domains by using the vserver cifs domain trusts show command.

```
vserver cifs domain trusts show -vserver vs1
```

|              |                                                        |
|--------------|--------------------------------------------------------|
| Node: node1  |                                                        |
| Vserver: vs1 |                                                        |
| Home Domain  | Trusted Domain                                         |
| -----        | -----                                                  |
| EXAMPLE.COM  | CIFS1.EXAMPLE.COM,<br>CIFS2.EXAMPLE.COM<br>EXAMPLE.COM |
| Node: node2  |                                                        |
| Vserver: vs1 |                                                        |
| Home Domain  | Trusted Domain                                         |
| -----        | -----                                                  |
| EXAMPLE.COM  | CIFS1.EXAMPLE.COM,<br>CIFS2.EXAMPLE.COM<br>EXAMPLE.COM |

## Related information

[Resetting and rediscovering trusted domains](#)

[Add, remove, or replace trusted domains in preferred trusted domain lists](#)

You can add or remove trusted domains from the preferred trusted domain list for the SMB server or you can modify the current list. If you configure a preferred trusted domain list, this list is used instead of the discovered bidirectional trusted domains when performing multidomain name mapping searches.

## About this task

- If you are adding trusted domains to an existing list, the new list is merged with the existing list with the new entries placed at the end. The trusted domains are searched in the order they appear in the trusted domain list.
- If you are removing trusted domains from the existing list and do not specify a list, the entire trusted domain list for the specified storage virtual machine (SVM) is removed.
- If you modify the existing list of trusted domains, the new list overwrites the existing list.

 You should enter only bidirectionally trusted domains in the preferred trusted domain list. Even though you can enter outbound or inbound trust domains into the preferred domain list, they are not used when performing multidomain name mapping searches. ONTAP skips the entry for the unidirectional domain and moves on to the next bidirectional trusted domain in the list.

## Step

1. Perform one of the following actions:

| If you want to do the following with the list of preferred trusted domains... | Use the command...                                                                                  |
|-------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------|
| Add trusted domains to the list                                               | vserver cifs domain name-mapping-search add -vserver _vserver_name_-trusted-domains FQDN, ...       |
| Remove trusted domains from the list                                          | vserver cifs domain name-mapping-search remove -vserver _vserver_name_ [-trusted-domains FQDN, ...] |
| Modify the existing list                                                      | vserver cifs domain name-mapping-search modify -vserver _vserver_name_-trusted-domains FQDN, ...    |

## Examples

The following command adds two trusted domains (cifs1.example.com and cifs2.example.com) to the preferred trusted domain list used by SVM vs1:

```
cluster1::> vserver cifs domain name-mapping-search add -vserver vs1
-trusted-domains cifs1.example.com, cifs2.example.com
```

The following command removes two trusted domains from the list used by SVM vs1:

```
cluster1::> vserver cifs domain name-mapping-search remove -vserver vs1
-trusted-domains cifs1.example.com, cifs2.example.com
```

The following command modifies the trusted domain list used by SVM vs1. The new list replaces the original list:

```
cluster1::> vserver cifs domain name-mapping-search modify -vserver vs1
-trusted-domains cifs3.example.com
```

## Related information

[Displaying information about the preferred trusted domain list](#)

[Display information about the preferred trusted domain list](#)

You can display information about which trusted domains are in the preferred trusted domain list and the order in which they are searched if multidomain name mapping searches are enabled. You can configure a preferred trusted domain list as an alternative

to using the automatically discovered trusted domain list.

## Steps

1. Perform one of the following actions:

| If you want to display information about the following...                             | Use the command...                                                        |
|---------------------------------------------------------------------------------------|---------------------------------------------------------------------------|
| All preferred trusted domains in the cluster grouped by storage virtual machine (SVM) | vserver cifs domain name-mapping-search show                              |
| All preferred trusted domains for a specified SVM                                     | vserver cifs domain name-mapping-search show -vserver <i>vserver_name</i> |

The following command displays information about all preferred trusted domains on the cluster:

```
cluster1::> vserver cifs domain name-mapping-search show
Vserver Trusted Domains

vs1 CIFS1.EXAMPLE.COM
```

## Create and configure SMB shares

### Create and configure SMB shares overview

Before users and applications can access data on the CIFS server over SMB, you must create and configure SMB shares, which is a named access point in a volume. You can customize shares by specifying share parameters and share properties. You can modify an existing share at any time.

When you create an SMB share, ONTAP creates a default ACL for the share with Full Control permissions for Everyone.

SMB shares are tied to the CIFS server on the storage virtual machine (SVM). SMB shares are deleted if either the SVM is deleted or the CIFS server with which it is associated is deleted from the SVM. If you recreate the CIFS server on the SVM, you must re-create the SMB shares.

## Related information

[Configure character mapping for SMB file name translation on volumes](#)

## What the default administrative shares are

When you create a CIFS server on your storage virtual machine (SVM), default administrative shares are automatically created. You should understand what those default shares are and how they are used.

ONTAP creates the following default administrative shares when you create the CIFS server:

Beginning with ONTAP 9.8, the admin\$ share is no longer created by default.

- ipc\$
- admin\$ (ONTAP 9.7 and earlier only)
- c\$

Because shares that end with the \$ character are hidden shares, the default administrative shares are not visible from My Computer, but you can view them by using Shared Folders.

## How the ipc\$ and admin\$ default shares are used

The ipc\$ and admin\$ shares are used by ONTAP and cannot be used by Windows administrators to access data residing on the SVM.

- ipc\$ share

The ipc\$ share is a resource that shares the named pipes that are essential for communication between programs. The ipc\$ share is used during remote administration of a computer and when viewing a computer's shared resources. You cannot change the share settings, share properties, or ACLs of the ipc\$ share. You also cannot rename or delete the ipc\$ share.

- admin\$ share (ONTAP 9.7 and earlier only)

Beginning with ONTAP 9.8, the admin\$ share is no longer created by default.

The admin\$ share is used during remote administration of the SVM. The path of this resource is always the path to the SVM root. You cannot change the share settings, share properties, or ACLs for the admin\$ share. You also cannot rename or delete the admin\$ share.

## How the c\$ default share is used

The c\$ share is an administrative share that the cluster or SVM administrator can use to access and manage the SVM root volume.

The following are characteristics of the c\$ share:

- The path for this share is always the path to the SVM root volume and cannot be modified.
- The default ACL for the c\$ share is Administrator / Full Control.

This user is the BUILTIN\administrator. By default, the BUILTIN\administrator can map to the share and view, create, modify, or delete files and folders in the mapped root directory. Caution should be exercised when managing files and folders in this directory.

- You can change the c\$ share's ACL.

- You can change the c\$ share settings and share properties.
- You cannot delete the c\$ share.
- The SVM administrator can access the rest of the SVM namespace from the mapped c\$ share by crossing the namespace junctions.
- The c\$ share can be accessed by using the Microsoft Management Console.

### SMB share naming requirements

You should keep the ONTAP share naming requirements in mind when creating SMB shares on your SMB server.

Share naming conventions for ONTAP are the same as for Windows and include the following requirements:

- The name of each share must be unique for the SMB server.
- Share names are not case-sensitive.
- The maximum share name length is 80 characters.
- Unicode share names are supported.
- Share names ending with the \$ character are hidden shares.
- For ONTAP 9.7 and earlier, the admin\$, ipc\$, and c\$ administrative shares are automatically created on every CIFS server and are reserved share names. Beginning with ONTAP 9.8, the admin\$ share is no longer automatically created.
- You cannot use the share name ONTAP\_ADMIN\$ when creating a share.
- Share names containing spaces are supported:
  - You cannot use a space as the first character or as the last character in a share name.
  - You must enclose share names containing a space in quotation marks.

Single quotation marks are considered part of the share name and cannot be used in place of quotation marks.

- The following special characters are supported when you name SMB shares:

! @ # % & '\_ - . ~ ( ) { }

- The following special characters are not supported when you name SMB shares:

"/\:;|<>,?\*=

### Directory case-sensitivity requirements when creating shares in a multiprotocol environment

If you create shares in an SVM where the 8.3 naming scheme is used to distinguish between directory names where there are only case differences between the names, you must use the 8.3 name in the share path to ensure that the client connects to the desired directory path.

In the following example, two directories named “testdir” and “TESTDIR” were created on a Linux client. The

junction path of the volume containing the directories is /home. The first output is from a Linux client and the second output is from an SMB client.

```
ls -l
drwxrwxr-x 2 user1 group1 4096 Apr 17 11:23 testdir
drwxrwxr-x 2 user1 group1 4096 Apr 17 11:24 TESTDIR
```

```
dir
```

```
Directory of Z:\

04/17/2015 11:23 AM <DIR> testdir
04/17/2015 11:24 AM <DIR> TESTDI~1
```

When you create a share to the second directory, you must use the 8.3 name in the share path. In this example, the share path to the first directory is /home/testdir and the share path to the second directory is /home/TESTDI~1.

### Use SMB share properties

#### Use SMB share properties overview

You can customize the properties of SMB shares.

The available share properties are as follows:

| Share properties | Description                                                                                                                       |
|------------------|-----------------------------------------------------------------------------------------------------------------------------------|
| oplocks          | This property specifies that the share uses opportunistic locks, also known as client-side caching.                               |
| browsable        | This property allows Windows clients to browse the share.                                                                         |
| showsnapshot     | This property specifies that Snapshot copies can be viewed and traversed by clients.                                              |
| changenotify     | This property specifies that the share supports Change Notify requests. For shares on an SVM, this is a default initial property. |

| Share properties         | Description                                                                                                                                                                                                                                                                                                                                                                                                                                |
|--------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| attributecache           | This property enables the file attribute caching on the SMB share to provide faster access of attributes. The default is to disable attribute caching. This property should be enabled only if there are clients connecting to shares over SMB 1.0. This share property is not applicable if clients are connecting to shares over SMB 2.x or SMB 3.0.                                                                                     |
| continuously-available   | This property permits SMB clients that support it to open files in a persistent manner. Files opened this way are protected from disruptive events, such as failover and giveback.                                                                                                                                                                                                                                                         |
| branchcache              | This property specifies that the share allows clients to request BranchCache hashes on the files within this share. This option is useful only if you specify “per-share” as the operating mode in the CIFS BranchCache configuration.                                                                                                                                                                                                     |
| access-based-enumeration | This property specifies that <i>Access Based Enumeration</i> (ABE) is enabled on this share. ABE-filtered shared folders are visible to a user based on that individual user’s access rights, preventing the display of folders or other shared resources that the user does not have rights to access.                                                                                                                                    |
| namespace-caching        | This property specifies that the SMB clients connecting to this share can cache the directory enumeration results returned by the CIFS servers, which can provide better performance. By default, SMB 1 clients do not cache directory enumeration results. Because SMB 2 and SMB 3 clients cache directory enumeration results by default, specifying this share property provides performance benefits only to SMB 1 client connections. |
| encrypt-data             | This property specifies that SMB encryption must be used when accessing this share. SMB clients that do not support encryption when accessing SMB data will not be able to access this share.                                                                                                                                                                                                                                              |

### Add or remove share properties on an existing SMB share

You can customize an existing SMB share by adding or removing share properties. This can be useful if you want to change the share configuration to meet changing requirements in your environment.

#### Before you begin

The share whose properties you want to modify must exist.

## About this task

Guidelines for adding share properties:

- You can add one or more share properties by using a comma-delimited list.
- Any share properties that you have previously specified remain in effect.

Newly added properties are appended to the existing list of share properties.

- If you specify a new value for share properties that are already applied to the share, the newly specified value replaces the original value.
- You cannot remove share properties by using the `vserver cifs share properties add` command.

You can use the `vserver cifs share properties remove` command to remove share properties.

Guidelines for removing share properties:

- You can remove one or more share properties by using a comma-delimited list.
- Any share properties that you have previously specified but do not remove remain in effect.

## Steps

1. Enter the appropriate command:

| If you want to...       | Enter the command...                                                                                                                  |
|-------------------------|---------------------------------------------------------------------------------------------------------------------------------------|
| Add share properties    | <code>vserver cifs share properties add -vserver _vserver_name_ -share-name _share_name_ -share-properties _properties_,...</code>    |
| Remove share properties | <code>vserver cifs share properties remove -vserver _vserver_name_ -share-name _share_name_ -share-properties _properties_,...</code> |

2. Verify the share property settings: `vserver cifs share show -vserver vserver_name -share-name share_name`

## Examples

The following command adds the `showsnapshot` share property to a share named “share1” on SVM vs1:

```

cluster1::> vserver cifs share properties add -vserver vs1 -share-name
share1 -share-properties showsnapshot

cluster1::> vserver cifs share show -vserver vs1
Vserver Share Path Properties Comment ACL
----- ----- ----- ----- -----
vs1 share1 /share1 oplocks - Everyone / Full
Control
 browsable
 changenotify
 showsnapshot

```

The following command removes the browsable share property from a share named “share2” on SVM vs1:

```

cluster1::> vserver cifs share properties remove -vserver vs1 -share-name
share2 -share-properties browsable

cluster1::> vserver cifs share show -vserver vs1
Vserver Share Path Properties Comment ACL
----- ----- ----- ----- -----
vs1 share2 /share2 oplocks - Everyone / Full
Control
 changenotify

```

## Related information

[Commands for managing SMB shares](#)

[Optimize SMB user access with the force-group share setting](#)

When you create a share from the ONTAP command line to data with UNIX effective security, you can specify that all files created by SMB users in that share belong to the same group, known as the *force-group*, which must be a predefined group in the UNIX group database. Using a force-group makes it easier to ensure that files can be accessed by SMB users belonging to various groups.

Specifying a force-group is meaningful only if the share is in a UNIX or mixed qtree. There is no need to set a force-group for shares in an NTFS volume or qtree because access to files in these shares is determined by Windows permissions, not UNIX GIDs.

If a force-group has been specified for a share, the following becomes true of the share:

- SMB users in the force-group who access this share are temporarily changed to the GID of the force-group.

This GID enables them to access files in this share that are not accessible normally with their primary GID or UID.

- All files in this share created by SMB users belong to the same force-group, regardless of the primary GID of the file owner.

When SMB users try to access a file created by NFS, the SMB users' primary GIDs determine access rights.

The force-group does not affect how NFS users access files in this share. A file created by NFS acquires the GID from the file owner. Determination of access permissions is based on the UID and primary GID of the NFS user who is trying to access the file.

Using a force-group makes it easier to ensure that files can be accessed by SMB users belonging to various groups. For example, if you want to create a share to store the company's web pages and give write access to users in the Engineering and Marketing departments, you can create a share and give write access to a force-group named "webgroup1". Because of the force-group, all files created by SMB users in this share are owned by the "webgroup1" group. In addition, users are automatically assigned the GID of the "webgroup1" group when accessing the share. As a result, all the users can write to this share without you needing to manage the access rights of the users in the Engineering and Marketing departments.

## Related information

[Creating an SMB share with the force-group share setting](#)

### Create an SMB share with the force-group share setting

You can create an SMB share with the force-group share setting if you want SMB users that access data on volumes or qtrees with UNIX file security to be regarded by ONTAP as belonging to the same UNIX group.

#### Step

1. Create the SMB share: `vserver cifs share create -vserver vserver_name -share-name share_name -path path -force-group-for-create UNIX_group_name`

If the UNC path (`\servername\sharename\filepath`) of the share contains more than 256 characters (excluding the initial "\\" in the UNC path), then the **Security** tab in the Windows Properties box is unavailable. This is a Windows client issue rather than an ONTAP issue. To avoid this issue, do not create shares with UNC paths with more than 256 characters.

If you want to remove the force-group after the share is created, you can modify the share at any time and specify an empty string ("") as the value for the `-force-group-for-create` parameter. If you remove the force-group by modifying the share, all existing connections to this share continue to have the previously set force-group as the primary GID.

#### Example

The following command creates a "webpages" share that is accessible on the web in the `/corp/companyinfo` directory in which all files that SMB users create are assigned to the webgroup1 group:

```
vserver cifs share create -vserver vs1 -share-name webpages -path
/corp/companyinfo -force-group-for-create webgroup1
```

## Related information

## **View information about SMB shares using the MMC**

You can view information about SMB shares on your SVM and perform some management tasks using the Microsoft Management Console (MMC). Before you can view the shares, you need to connect the MMC to the SVM.

### **About this task**

You can perform the following tasks on shares contained within SVMs using the MMC:

- View shares
- View active sessions
- View open files
- Enumerate the list of sessions, files and tree connections in the system
- Close open files in the system
- Close open sessions
- Create/manage shares

The views displayed by the preceding capabilities are node specific and not cluster specific. Therefore, when you use the MMC to connect to the SMB server host name (that is, cifs01.domain.local), you are routed, based on how you have set up DNS, to a single LIF within your cluster.

The following functions are not supported in MMC for ONTAP:

- Creating new local users/groups
- Managing/viewing existing local users/groups
- Viewing events or performance logs
- Storage
- Services and applications

In instances where the operation is not supported, you might experience remote procedure call failed errors.

## [FAQ: Using Windows MMC with ONTAP](#)

### **Steps**

1. To open Computer Management MMC on any Windows server, in the **Control Panel**, select **Administrative Tools > Computer Management**.
2. Select **Action > Connect to another computer**.

The Select Computer dialog box appears.

3. Type the name of the storage system or click **Browse** to locate the storage system.
4. Click **OK**.

The MMC connects to the SVM.

5. In the navigation pane, click **Shared Folders > Shares**.

A list of shares on the SVM is displayed in the right display pane.

6. To display the share properties for a share, double-click the share to open the **Properties** dialog box.
7. If you cannot connect to the storage system using MMC, you can add the user to the BUILTIN\Administrators group or BUILTIN\Power Users group by using one of the following commands on the storage system:

```
cifs users-and-groups local-groups add-members -vserver <vserver_name>
-group-name BUILTIN\Administrators -member-names <domainuser>
```

```
cifs users-and-groups local-groups add-members -vserver <vserver_name>
-group-name "BUILTIN\Power Users" -member-names <domainuser>
```

#### Commands for managing SMB shares

You use the vserver cifs share and vserver cifs share properties commands to manage SMB shares.

| If you want to...                              | Use this command...                  |
|------------------------------------------------|--------------------------------------|
| Create an SMB share                            | vserver cifs share create            |
| Display SMB shares                             | vserver cifs share show              |
| Modify an SMB share                            | vserver cifs share modify            |
| Delete an SMB share                            | vserver cifs share delete            |
| Add share properties to an existing share      | vserver cifs share properties add    |
| Remove share properties from an existing share | vserver cifs share properties remove |
| Display information about share properties     | vserver cifs share properties show   |

See the man page for each command for more information.

#### Secure file access by using SMB share ACLs

You can change share-level ACLs to give users more or less access rights to the share. You can configure share-level ACLs by using either Windows users and groups or UNIX users and groups.

After you create a share, by default, the share-level ACL gives read access to the standard group named Everyone. Read access in the ACL means that all users in the domain and all trusted domains have read-only

access to the share.

You can change a share-level ACL by using the Microsoft Management Console (MMC) on a Windows client or the ONTAP command line.

The following guidelines apply when you use the MMC:

- The user and group names specified must be Windows names.
- You can specify only Windows permissions.

The following guidelines apply when you use the ONTAP command line:

- The user and group names specified can be Windows names or UNIX names.

If a user and group type is not specified when creating or modifying ACLs, the default type is Windows users and groups.

- You can specify only Windows permissions.

#### Create SMB share access control lists

Configuring share permissions by creating access control lists (ACLs) for SMB shares enables you to control the level of access to a share for users and groups.

#### About this task

You can configure share-level ACLs by using local or domain Windows user or group names or UNIX user or group names.

Before creating a new ACL, you should delete the default share ACL Everyone / Full Control, which poses a security risk.

In workgroup mode, the local domain name is the SMB server name.

#### Steps

1. Delete the default share ACL: `vserver cifs share access-control delete -vserver *vserver\_name* -share *share\_name* -user-or-group Everyone`
2. Configure the new ACL:

| If you want to configure ACLs by using a... | Enter the command...                                                                                                                                                                                                   |
|---------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Windows user                                | <pre>vserver cifs share access-control create -vserver <i>vserver_name</i> -share <i>share_name</i> -user-group-type windows -user-or-group <i>Windows_domain_name\user_name</i> -permission <i>access_right</i></pre> |

| If you want to configure ACLs by using a... | Enter the command...                                                                                                                                                                            |
|---------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Windows group                               | vserver cifs share access-control<br>create -vserver vserver_name -share<br>share_name -user-group-type windows<br>-user-or-group<br>Windows_domain_name\group_name<br>-permission access_right |
| UNIX user                                   | vserver cifs share access-control<br>create -vserver vserver_name -share<br>share_name -user-group-type unix-user<br>-user-or-group UNIX_user_name<br>-permission access_right                  |
| UNIX group                                  | vserver cifs share access-control<br>create -vserver vserver_name -share<br>share_name -user-group-type unix-group<br>-user-or-group UNIX_group_name<br>-permission access_right                |

3. Verify that the ACL applied to the share is correct by using the `vserver cifs share access-control show` command.

### Example

The following command gives Change permissions to the “Sales Team” Windows group for the “sales” share on the “`vs1.example.com`” SVM:

```
cluster1::> vserver cifs share access-control create -vserver
vs1.example.com -share sales -user-or-group "DOMAIN\Sales Team"
-permission Change

cluster1::> vserver cifs share access-control show -vserver
vs1.example.com
 Share User/Group User/Group Access
 Name Name Type
Vserver
Permission

vs1.example.com c$ BUILTIN\Administrators windows
Full_Control
vs1.example.com sales DOMAIN\Sales Team windows Change
```

The following command gives Read permission to the “engineering” UNIX group for the “eng” share on the “`vs2.example.com`” SVM:

```

cluster1::> vserver cifs share access-control create -vserver
vs2.example.com -share eng -user-group-type unix-group -user-or-group
engineering -permission Read

cluster1::> vserver cifs share access-control show -vserver
vs2.example.com

 Share User/Group User/Group Access
Vserver Name Name Type
Permission

vs2.example.com c$ BUILTIN\Administrators windows
Full_Control
vs2.example.com eng engineering unix-group Read

```

The following commands give Change permission to the local Windows group named “Tiger Team” and Full\_Control permission to the local Windows user named “Sue Chang” for the “datavol5” share on the “`vs1`” SVM:

```

cluster1::> vserver cifs share access-control create -vserver vs1 -share
datavol5 -user-group-type windows -user-or-group "Tiger Team" -permission
Change

cluster1::> vserver cifs share access-control create -vserver vs1 -share
datavol5 -user-group-type windows -user-or-group "Sue Chang" -permission
Full_Control

cluster1::> vserver cifs share access-control show -vserver vs1

 Share User/Group User/Group Access
Vserver Name Name Type
Permission

vs1 c$ BUILTIN\Administrators windows
Full_Control
vs1 datavol5 Tiger Team windows Change
vs1 datavol5 Sue Chang windows Full_Control

```

#### **Commands for managing SMB share access control lists**

You need to know the commands for managing SMB access control lists (ACLs), which includes creating, displaying, modifying, and deleting them.

| If you want to... | Use this command...                      |
|-------------------|------------------------------------------|
| Create a new ACL  | vserver cifs share access-control create |
| Display ACLs      | vserver cifs share access-control show   |
| Modify an ACL     | vserver cifs share access-control modify |
| Delete an ACL     | vserver cifs share access-control delete |

## Secure file access by using file permissions

### Configure advanced NTFS file permissions using the Windows Security tab

You can configure standard NTFS file permissions on files and folders by using the **Windows Security** tab in the Windows Properties window.

#### Before you begin

The administrator performing this task must have sufficient NTFS permissions to change permissions on the selected objects.

#### About this task

Configuring NTFS file permissions is done on a Windows host by adding entries to NTFS discretionary access control lists (DACLs) that are associated with an NTFS security descriptor. The security descriptor is then applied to NTFS files and directories. These tasks are automatically handled by the Windows GUI.

#### Steps

1. From the **Tools** menu in Windows Explorer, select **Map network drive**.
2. Complete the **Map Network Drive** dialog box:
  - a. Select a **Drive** letter.
  - b. In the **Folder** box, type the CIFS server name containing the share that contains the data to which you want to apply permissions and the name of the share.

If your CIFS server name is “CIFS\_SERVER” and your share is named “share1”, you should type \\CIFS\_SERVER\share1.

You can specify the IP address of the data interface for the CIFS server instead of the CIFS server name.

- c. Click **Finish**.

The drive you selected is mounted and ready with the Windows Explorer window displaying files and folders contained within the share.

3. Select the file or directory for which you want to set NTFS file permissions.

4. Right-click the file or directory, and then select **Properties**.

5. Select the **Security** tab.

The **Security** tab displays the list of users and groups for which NTFS permission are set. The **Permissions for** box displays a list of Allow and Deny permissions in effect for each user or group selected.

6. Click **Advanced**.

The Windows Properties window displays information about existing file permissions assigned to users and groups.

7. Click **Change Permissions**.

The Permissions window opens.

8. Perform the desired actions:

| If you want to...                                        | Do the following...                                                                                                                                                                                            |
|----------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Set up advanced NTFS permissions for a new user or group | <ol style="list-style-type: none"><li>Click <b>Add</b>.</li><li>In the <b>Enter the object name to select</b> box, type the name of the user or group that you want to add.</li><li>Click <b>OK</b>.</li></ol> |
| Change advanced NTFS permissions from a user or group    | <ol style="list-style-type: none"><li>In the <b>Permissions entries:</b> box, select the user or group whose advanced permissions you want to change.</li><li>Click <b>Edit</b>.</li></ol>                     |
| Remove advanced NTFS permissions for a user or group     | <ol style="list-style-type: none"><li>In the <b>Permissions entries:</b> box, select the user or group that you want to remove.</li><li>Click <b>Remove</b>.</li><li>Skip to Step 13.</li></ol>                |

If you are adding advanced NTFS permissions on a new user or group or changing NTFS advanced permissions on an existing user or group, the Permission Entry for <Object> box opens.

9. In the **Apply to** box, select how you want to apply this NTFS file permission entry.

If you are setting up NTFS file permissions on a single file, the **Apply to** box is not active. The **Apply to** setting defaults to **This object only**.

10. In the **Permissions** box, select the **Allow** or **Deny** boxes for the advanced permissions that you want to set on this object.

◦ To allow the specified access, select the **Allow** box.

◦ To not allow the specified access, select the **Deny** box.

You can set permissions on the following advanced rights:

- **Full control**

If you choose this advanced right, all other advanced rights are automatically chosen (either Allow or Deny rights).

- **Traverse folder / execute file**
- **List folder / read data**
- **Read attributes**
- **Read extended attributes**
- **Create files / write data**
- **Create folders / append data**
- **Write attributes**
- **Write extended attributes**
- **Delete subfolders and files**
- **Delete**
- **Read permissions**
- **Change permissions**
- **Take ownership**

If any of the advanced permission boxes are not selectable, it is because the permissions are inherited from the parent object.

11. If you want subfolders and files of this object to inherit these permissions, select the **Apply these permissions to objects and/or containers within this container only** box.
12. Click **OK**.
13. After you finish adding, removing, or editing NTFS permissions, specify the inheritance setting for this object:
  - Select the **Include inheritable permissions from this object's parent** box.  
This is the default.
  - Select the **Replace all child object permissions with inheritable permissions from this object** box.

This setting is not present in the Permissions box if you are setting NTFS file permissions on a single file.

Be cautious when selecting this setting. This setting removes all existing permissions on all child objects and replaces them with this object's permission settings. You could inadvertently remove permissions that you did not want removed. It is especially important when setting permissions in a mixed security-style volume or qtree. If child objects have a UNIX effective security style, propagating NTFS permissions to those child objects results in ONTAP changing these objects from UNIX security style to NTFS security style, and all UNIX permissions on those child objects are replaced with NTFS permissions.

- Select both boxes.
- Select neither box.

14. Click **OK** to close the **Permissions** box.
15. Click **OK** to close the **Advanced Security settings for <Object>** box.

For more information about how to set advanced NTFS permissions, see your Windows documentation.

#### Related information

[Configure and apply file security on NTFS files and folders using the CLI](#)

[Displaying information about file security on UNIX security-style volumes](#)

#### [Configure NTFS file permissions using the ONTAP CLI](#)

You can configure NTFS file permissions on files and directories using the ONTAP CLI. This enables you to configure NTFS file permissions without needing to connect to the data using an SMB share on a Windows Client.

You can configure NTFS file permissions by adding entries to NTFS discretionary access control lists (DACLs) that are associated with an NTFS security descriptor. The security descriptor is then applied to NTFS files and directories.

You can only configure NTFS file permissions using the command line. You cannot configure NFSv4 ACLs by using the CLI.

#### Steps

1. Create an NTFS security descriptor.

```
vserver security file-directory ntfs create -vserver svm_name -ntfs-sd
 ntfs_security_descriptor_name -owner owner_name -group primary_group_name
 -control-flags-raw raw_control_flags
```

2. Add DACLs to the NTFS security descriptor.

```
vserver security file-directory ntfs dacl add -vserver svm_name -ntfs-sd
 ntfs_security_descriptor_name -access-type {deny|allow} -account account_name
 -rights {no-access|full-control|modify|read-and-execute|read|write} -apply-to
 {this-folder|sub-folders|files}
```

3. Create a file/directory security policy.

```
vserver security file-directory policy create -vserver svm_name -policy-name
 policy_name
```

#### **How UNIX file permissions provide access control when accessing files over SMB**

A FlexVol volume can have one of three types of security style: NTFS, UNIX, or mixed. You can access data over SMB regardless of security style; however, appropriate UNIX file permissions are needed to access data with UNIX effective security.

When data is accessed over SMB, there are several access controls used when determining whether a user is authorized to perform a requested action:

- Export permissions

Configuring export permissions for SMB access is optional.

- Share permissions
- File permissions

The following types of file permissions might be applied to the data on which the user wants to perform an action:

- NTFS
- UNIX NFSv4 ACLs
- UNIX mode bits

For data with NFSv4 ACLs or UNIX mode bits set, UNIX style permissions are used to determine file access rights to the data. The SVM administrator needs to set the appropriate file permission to ensure that users have the rights to perform the desired action.

Data in a mixed security-style volume might have either NTFS or UNIX effective security style. If the data has UNIX effective security style, then NFSv4 permissions or UNIX mode bits are used when determining file access rights to the data.

## Secure file access by using Dynamic Access Control (DAC)

### Secure file access by using Dynamic Access Control (DAC) overview

You can secure access by using Dynamic Access Control and by creating central access policies in Active Directory and applying them to files and folders on SVMs through applied Group Policy Objects (GPOs). You can configure auditing to use central access policy staging events to see the effects of changes to central access policies before you apply them.

### Additions to CIFS credentials

Before Dynamic Access Control, a CIFS credential included a security principal's (the user's) identity and Windows group membership. With Dynamic Access Control, three more types of information are added to the credential—device identity, device claims, and user claims:

- Device identity

The analog of the user's identity information, except it is the identity and group membership of the device that the user is logging in from.

- Device claims

Assertions about a device security principal. For example, a device claim might be that it is a member of a specific OU.

- User claims

Assertions about a user security principal. For example, a user claim might be that their AD account is a member of a specific OU.

## Central access policies

Central access policies for files enable organizations to centrally deploy and manage authorization policies that include conditional expressions using user groups, user claims, device claims, and resource properties.

For example, for accessing high business impact data, a user needs to be a full time employee and only have access to the data from a managed device. Central access policies are defined in Active Directory and distributed to file servers via the GPO mechanism.

### Central access policy staging with advanced auditing

Central access policies can be “staged”, in which case they are evaluated in a “what-if” manner during file access checks. The results of what would have happened if the policy was in effect and how that differs from what is currently configured are logged as an audit event. In this way, administrators can use audit event logs to study the impact of an access policy change before actually putting the policy in play. After evaluating the impact of an access policy change, the policy can be deployed via GPOs to the desired SVMs.

##### [Supported Dynamic Access Control functionality](#)

If you want to use Dynamic Access Control (DAC) on your CIFS server, you need to understand how ONTAP supports Dynamic Access Control functionality in Active Directory environments.

##### [Supported for Dynamic Access Control](#)

ONTAP supports the following functionality when Dynamic Access Control is enabled on the CIFS server:

| Functionality                                                                                  | Comments                                                                                                                                                                                                                                                                                                                                                                                                       |
|------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Claims into the file system                                                                    | Claims are simple name and value pairs that state some truth about a user. User credentials now contain claim information, and security descriptors on files can perform access checks that include claims checks. This gives administrators a finer level of control over who can access files.                                                                                                               |
| Conditional expressions to file access checks                                                  | When modifying the security parameters of a file, users can now add arbitrarily complex conditional expressions to the file's security descriptor. The conditional expression can include checks for claims.                                                                                                                                                                                                   |
| Central control of file access via central access policies                                     | Central access policies are a kind of ACL stored in Active Directory that can be tagged to a file. Access to the file is only granted if the access checks of both the security descriptor on disk and the tagged central access policy allows access. This gives administrators the ability to control access to files from a central location (AD) without having to modify the security descriptor on disk. |
| Central access policy staging                                                                  | Adds the ability to try out security changes without affecting actual file access, by "staging" a change to the central access policies, and seeing the effect of the change in an audit report.                                                                                                                                                                                                               |
| Support for displaying information about central access policy security by using the ONTAP CLI | Extends the <code>vserver security file-directory show</code> command to display information about applied central access policies.                                                                                                                                                                                                                                                                            |
| Security tracing that includes central access policies                                         | Extends the <code>vserver security trace</code> command family to display results that include information about applied central access policies.                                                                                                                                                                                                                                                              |

## Unsupported for Dynamic Access Control

ONTAP does not support the following functionality when Dynamic Access Control is enabled on the CIFS server:

| Functionality                                              | Comments                                                                                               |
|------------------------------------------------------------|--------------------------------------------------------------------------------------------------------|
| Automatic classification of NTFS file system objects       | This is an extension to the Windows File Classification Infrastructure that is not supported in ONTAP. |
| Advanced auditing other than central access policy staging | Only central access policy staging is supported for advanced auditing.                                 |

## **Considerations when using Dynamic Access Control and central access policies with CIFS servers**

There are certain considerations you must keep in mind when using Dynamic Access Control (DAC) and central access policies to secure files and folders on CIFS servers.

### **NFS access can be denied to root if policy rule applies to domain\administrator user**

Under certain circumstances, NFS access to root might be denied when central access policy security is applied to the data that the root user is attempting to access. The issue occurs when the central access policy contains a rule that is applied to the domain\administrator and the root account is mapped to the domain\administrator account.

Instead of applying a rule to the domain\administrator user, you should apply the rule to a group with administrative privileges, such as the domain\administrators group. In this way, you can map root to the domain\administrator account without root being impacted by this issue.

### **CIFS server's BUILTIN\Administrators group has access to resources when the applied central access policy is not found in Active Directory**

It is possible that resources contained within the CIFS server have central access policies applied to them, but when the CIFS server uses the central access policy's SID to attempt to retrieve information from Active Directory, the SID does not match any existing central access policy SIDs in Active Directory. Under these circumstances, the CIFS server applies the local default recovery policy for that resource.

The local default recovery policy allows the CIFS server's BUILTIN\Administrators group access to that resource.

### **Enable or disable Dynamic Access Control overview**

The option that enables you to use Dynamic Access Control (DAC) to secure objects on your CIFS server is disabled by default. You must enable the option if you want to use Dynamic Access Control on your CIFS server. If you later decide that you do not want to use Dynamic Access Control to secure objects stored on the CIFS server, you can disable the option.

#### **About this task**

Once Dynamic Access Control is enabled, the file system can contain ACLs with Dynamic Access Control-related entries. If Dynamic Access Control is disabled, the current Dynamic Access Control entries will be ignored, and new ones will not be allowed.

This option is available only at the advanced privilege level.

#### **Step**

1. Set the privilege level to advanced: set -privilege advanced
2. Perform one of the following actions:

| If you want Dynamic Access Control to be... | Enter the command...                                                                |
|---------------------------------------------|-------------------------------------------------------------------------------------|
| Enabled                                     | <code>vserver cifs options modify -vserver vserver_name -is-dac-enabled true</code> |

|          |                                                                                        |
|----------|----------------------------------------------------------------------------------------|
| Disabled | <pre>vserver cifs options modify -vserver<br/>vserver_name -is-dac-enabled false</pre> |
|----------|----------------------------------------------------------------------------------------|

3. Return to the administrator privilege level: `set -privilege admin`

[Configuring central access policies to secure data on CIFS servers](#)

### Manage ACLs that contain Dynamic Access Control ACEs when Dynamic Access Control is disabled

If you have resources that have ACLs applied with Dynamic Access Control ACEs and you disable Dynamic Access Control on the storage virtual machine (SVM), you must remove the Dynamic Access Control ACEs before you can manage the non-Dynamic Access Control ACEs on that resource.

#### About this task

After Dynamic Access Control is disabled, you cannot remove existing non-Dynamic Access Control ACEs or add new non-Dynamic Access Control ACEs until you have removed the existing Dynamic Access Control ACEs.

You can use whichever tool you normally use to manage ACLs to perform these steps.

#### Steps

1. Determine what Dynamic Access Control ACEs are applied to the resource.
2. Remove the Dynamic Access Control ACEs from the resource.
3. Add or remove non-Dynamic Access Control ACEs as desired from the resource.

### Configure central access policies to secure data on CIFS servers

There are several steps that you must take to secure access to data on the CIFS server using central access policies, including enabling Dynamic Access Control (DAC) on the CIFS server, configuring central access policies in Active Directory, applying the central access policies to Active Directory containers with GPOs, and enabling GPOs on the CIFS server.

#### Before you begin

- The Active Directory must be configured to use central access policies.
- You must have sufficient access on the Active Directory domain controllers to create central access policies and to create and apply GPOs to the containers that contain the CIFS servers.
- You must have sufficient administrative access on the storage virtual machine (SVM) to execute the necessary commands.

#### About this task

Central access policies are defined and applied to group policy objects (GPOs) on Active Directory. You can consult the Microsoft TechNet Library for instructions about configuring central access policies and GPOs.

[Microsoft TechNet Library](#)

## Steps

1. Enable Dynamic Access Control on the SVM if it is not already enabled by using the `vserver cifs options modify` command.

```
vserver cifs options modify -vserver vs1 -is-dac-enabled true
```

2. Enable group policy objects (GPOs) on the CIFS server if they are not already enabled by using the `vserver cifs group-policy modify` command.

```
vserver cifs group-policy modify -vserver vs1 -status enabled
```

3. Create central access rules and central access policies on Active Directory.

4. Create a group policy object (GPO) to deploy the central access policies on Active Directory.

5. Apply the GPO to the container where the CIFS server computer account is located.

6. Manually update the GPOs applied to the CIFS server by using the `vserver cifs group-policy update` command.

```
vserver cifs group-policy update -vserver vs1
```

7. Verify that the GPO central access policy is applied to the resources on the CIFS server by using the `vserver cifs group-policy show-applied` command.

The following example shows that the Default Domain Policy has two central access policies that are applied to the CIFS server:

```
vserver cifs group-policy show-applied
```

```
Vserver: vs1

## Related information

[Displaying information about GPO configurations](#)

[Displaying information about central access policies](#)

[Displaying information about central access policy rules](#)

[Enabling or disabling Dynamic Access Control](#)

[Display information about Dynamic Access Control security](#)

You can display information about Dynamic Access Control (DAC) security on NTFS volumes and on data with NTFS effective security on mixed security-style volumes. This includes information about conditional ACEs, resource ACEs, and central access policy ACEs. You can use the results to validate your security configuration or to troubleshoot file access issues.

## About this task

You must supply the name of the storage virtual machine (SVM) and the path to the data whose file or folder security information you want to display. You can display the output in summary form or as a detailed list.

### Step

1. Display file and directory security settings with the desired level of detail:

| If you want to display information... | Enter the following command...                                                         |
|---------------------------------------|----------------------------------------------------------------------------------------|
| In summary form                       | <code>vserver security file-directory show<br/>-vserver vserver_name -path path</code> |

| If you want to display information...                                                                                      | Enter the following command...                                                                                 |
|----------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------|
| With expanded detail                                                                                                       | <code>vserver security file-directory show<br/>-vserver vserver_name -path path<br/>-expand-mask true</code>   |
| Where output is displayed with group and user SIDs                                                                         | <code>vserver security file-directory show<br/>-vserver vserver_name -path path<br/>-lookup-names false</code> |
| About file and directory security for files and directories where the hexadecimal bit mask is translated to textual format | <code>vserver security file-directory show<br/>-vserver vserver_name -path path<br/>-textual-mask true</code>  |

## Examples

The following example displays Dynamic Access Control security information about the path /vol1 in SVM vs1:

## Revert considerations for Dynamic Access Control

You should be aware of what happens when reverting to a version of ONTAP that does not support Dynamic Access Control (DAC) and what you must do before and after reverting.

If you want to revert the cluster to a version of ONTAP that does not support Dynamic Access Control and Dynamic Access Control is enabled on one or more the storage virtual machines (SVMs), you must do the following before reverting:

- You must disable Dynamic Access Control on all SVMs that have it enabled on the cluster.
- You must modify any auditing configurations on the cluster that contain the `cap-staging` event type to use only the `file-op` event type.

You must understand and act on some important revert considerations for files and folders with Dynamic Access Control ACEs:

- If the cluster is reverted, existing Dynamic Access Control ACEs are not removed; however, they will be ignored in file access checks.
- Since Dynamic Access Control ACEs are ignored after reversion, access to files will change on files with Dynamic Access Control ACEs.

This could allow users to access files they previously could not, or not be able to access files that they previously could.

- You should apply non-Dynamic Access Control ACEs to the affected files to restore their previous level of security.

This can be done either before reverting or immediately after reversion completes.

 Since Dynamic Access Control ACEs are ignored after reversion, it is not required that you remove them when applying non-Dynamic Access Control ACEs to the affected files. However, if desired, you can manually remove them.

#### Where to find additional information about configuring and using Dynamic Access Control and central access policies

Additional resources are available to help you configure and use Dynamic Access Control and central access policies.

You can find information about how to configure Dynamic Access Control and central access policies on Active Directory in the Microsoft TechNet Library.

[Microsoft TechNet: Dynamic Access Control Scenario Overview](#)

[Microsoft TechNet: Central Access Policy Scenario](#)

The following references can help you configure the SMB server to use and support Dynamic Access Control and central access policies:

- **Using GPOs on the SMB server**

[Applying Group Policy Objects to SMB servers](#)

- **Configuring NAS auditing on the SMB server**

[SMB and NFS auditing and security tracing](#)

## Secure SMB access using export policies

### How export policies are used with SMB access

If export policies for SMB access are enabled on the SMB server, export policies are used when controlling access to SVM volumes by SMB clients. To access data, you can create an export policy that allows SMB access and then associate the policy with the volumes containing SMB shares.

An export policy has one or more rules applied to it that specifies which clients are allowed access to the data and what authentication protocols are supported for read-only and read-write access. You can configure export policies to allow access over SMB to all clients, a subnet of clients, or a specific client and to allow authentication using Kerberos authentication, NTLM authentication, or both Kerberos and NTLM authentication when determining read-only and read-write access to data.

After processing all export rules applied to the export policy, ONTAP can determine whether the client is granted access and what level of access is granted. Export rules apply to client machines, not to Windows users and groups. Export rules do not replace Windows user and group-based authentication and authorization. Export rules provide another layer of access security in addition to share and file-access permissions.

You associate exactly one export policy to each volume to configure client access to the volume. Each SVM can contain multiple export policies. This enables you to do the following for SVMs with multiple volumes:

- Assign different export policies to each volume of the SVM for individual client access control to each volume in the SVM.
- Assign the same export policy to multiple volumes of the SVM for identical client access control without having to create a new export policy for each volume.

Each SVM has at least one export policy called “default”, which contains no rules. You cannot delete this export policy, but you can rename or modify it. Each volume on the SVM by default is associated with the default export policy. If export policies for SMB access is disabled on the SVM, the “default” export policy has no effect on SMB access.

You can configure rules that provide access to both NFS and SMB hosts and associate that rule with an export policy, which can then be associated with the volume that contains data to which both NFS and SMB hosts need access. Alternatively, if there are some volumes where only SMB clients require access, you can configure an export policy with rules that only allow access using the SMB protocol and that uses only Kerberos or NTLM (or both) for authentication for read-only and write access. The export policy is then associated to the volumes where only SMB access is desired.

If export policies for SMB is enabled and a client makes an access request that is not permitted by the applicable export policy, the request fails with a permission-denied message. If a client does not match any rule in the volume’s export policy, then access is denied. If an export policy is empty, then all accesses are implicitly denied. This is true even if the share and file permissions would otherwise permit access. This means that you must configure your export policy to minimally allow the following on volumes containing SMB shares:

- Allow access to all clients or the appropriate subset of clients
- Allow access over SMB
- Allow appropriate read-only and write access by using Kerberos or NTLM authentication (or both)

Learn about [configuring and managing export policies](#).

## How export rules work

Export rules are the functional elements of an export policy. Export rules match client access requests to a volume against specific parameters you configure to determine how to handle the client access requests.

An export policy must contain at least one export rule to allow access to clients. If an export policy contains more than one rule, the rules are processed in the order in which they appear in the export policy. The rule order is dictated by the rule index number. If a rule matches a client, the permissions of that rule are used and no further rules are processed. If no rules match, the client is denied access.

You can configure export rules to determine client access permissions using the following criteria:

- The file access protocol used by the client sending the request, for example, NFSv4 or SMB.
- A client identifier, for example, host name or IP address.

The maximum size for the `-clientmatch` field is 4096 characters.

- The security type used by the client to authenticate, for example, Kerberos v5, NTLM, or AUTH\_SYS.

If a rule specifies multiple criteria, the client must match all of them for the rule to apply.

### Example

The export policy contains an export rule with the following parameters:

- `-protocol nfs3`
- `-clientmatch 10.1.16.0/255.255.255.0`
- `-rorule any`
- `-rwrule any`

The client access request is sent using the NFSv3 protocol and the client has the IP address 10.1.17.37.

Even though the client access protocol matches, the IP address of the client is in a different subnet from the one specified in the export rule. Therefore, client matching fails and this rule does not apply to this client.

### Example

The export policy contains an export rule with the following parameters:

- `-protocol nfs`
- `-clientmatch 10.1.16.0/255.255.255.0`
- `-rorule any`
- `-rwrule any`

The client access request is sent using the NFSv4 protocol and the client has the IP address 10.1.16.54.

The client access protocol matches and the IP address of the client is in the specified subnet. Therefore, client matching is successful and this rule applies to this client. The client gets read-write access regardless of its security type.

### Example

The export policy contains an export rule with the following parameters:

- -protocol nfs3
- -clientmatch 10.1.16.0/255.255.255.0
- -rorule any
- -rwrule krb5,ntlm

Client #1 has the IP address 10.1.16.207, sends an access request using the NFSv3 protocol, and authenticated with Kerberos v5.

Client #2 has the IP address 10.1.16.211, sends an access request using the NFSv3 protocol, and authenticated with AUTH\_SYS.

The client access protocol and IP address matches for both clients. The read-only parameter allows read-only access to all clients regardless of the security type they authenticated with. Therefore both clients get read-only access. However, only client #1 gets read-write access because it used the approved security type Kerberos v5 to authenticate. Client #2 does not get read-write access.

#### Examples of export policy rules that restrict or allow access over SMB

The examples show how to create export policy rules that restrict or allow access over SMB on an SVM that has export policies for SMB access enabled.

Export policies for SMB access are disabled by default. You need to configure export policy rules that restrict or allow access over SMB only if you have enabled export policies for SMB access.

#### Export rule for SMB access only

The following command creates an export rule on the SVM named "vs1" that has the following configuration:

- Policy name: cifs1
- Index number: 1
- Client match: Matches only clients on the 192.168.1.0/24 network
- Protocol: Only enables SMB access
- Read-only access: To clients using NTLM or Kerberos authentication
- Read-write access: To clients using Kerberos authentication

```
cluster1::> vserver export-policy rule create -vserver vs1 -policyname
cifs1 -ruleindex 1 -protocol cifs -clientmatch 192.168.1.0/255.255.255.0
-rorule krb5,ntlm -rwrule krb5
```

#### Export rule for SMB and NFS access

The following command creates an export rule on the SVM named "vs1" that has the following configuration:

- Policy name: cifsnfs1
- Index number: 2

- Client match: Matches all clients
- Protocol: SMB and NFS access
- Read-only access: To all clients
- Read-write access: To clients using Kerberos (NFS and SMB) or NTLM authentication (SMB)
- Mapping for UNIX user ID 0 (zero): Mapped to user ID 65534 (which typically maps to the user name nobody)
- Suid and sgid access: Allows

```
cluster1::> vserver export-policy rule create -vserver vs1 -policynname
cifsnfs1 -ruleindex 2 -protocol cifs,nfs -clientmatch 0.0.0.0/0 -rorule any
-rwrule krb5,ntlm -anon 65534 -allow-suid true
```

### Export rule for SMB access using NTLM only

The following command creates an export rule on the SVM named “vs1” that has the following configuration:

- Policy name: ntlm1
- Index number: 1
- Client match: Matches all clients
- Protocol: Only enables SMB access
- Read-only access: Only to clients using NTLM
- Read-write access: Only to clients using NTLM

 If you configure the read-only option or the read-write option for NTLM-only access, you must use IP address-based entries in the client match option. Otherwise, you receive access denied errors. This is because ONTAP uses Kerberos Service Principal Names (SPN) when using a host name to check on the client's access rights. NTLM authentication does not support SPN names.

```
cluster1::> vserver export-policy rule create -vserver vs1 -policynname
ntlm1 -ruleindex 1 -protocol cifs -clientmatch 0.0.0.0/0 -rorule ntlm
-rwrule ntlm
```

### Enable or disable export policies for SMB access

You can enable or disable export policies for SMB access on storage virtual machines (SVMs). Using export policies to control SMB access to resources is optional.

#### Before you begin

The following are the requirements for enabling export policies for SMB:

- The client must have a “PTR” record in DNS before you create the export rules for that client.
- An additional set of “A” and “PTR” records for host names is required if the SVM provides access to NFS clients and the host name you want to use for NFS access is different from the CIFS server name.

## About this task

When setting up a new CIFS server on your SVM, the use of export policies for SMB access is disabled by default. You can enable export policies for SMB access if you want to control access based on authentication protocol or on client IP addresses or host names. You can enable or disable export policies for SMB access at any time.

## Steps

1. Set the privilege level to advanced: `set -privilege advanced`
2. Enable or disable export policies:
  - Enable export policies: `vserver cifs options modify -vserver vserver_name -is-exportpolicy-enabled true`
  - Disable export policies: `vserver cifs options modify -vserver vserver_name -is-exportpolicy-enabled false`
3. Return to the admin privilege level: `set -privilege admin`

## Example

The following example enables the use of export policies to control SMB client access to resources on SVM vs1:

```
cluster1::> set -privilege advanced
Warning: These advanced commands are potentially dangerous; use them
only when directed to do so by technical support personnel.
Do you wish to continue? (y or n): y

cluster1::*> vserver cifs options modify -vserver vs1 -is-exportpolicy
-enabled true

cluster1::*> set -privilege admin
```

## Secure file access by using Storage-Level Access Guard

### Secure file access by using Storage-Level Access Guard

In addition to securing access by using native file-level and export and share security, you can configure Storage-Level Access Guard, a third layer of security applied by ONTAP at the volume level. Storage-Level Access Guard applies to access from all NAS protocols to the storage object to which it is applied.

Only NTFS access permissions are supported. For ONTAP to perform security checks on UNIX users for access to data on volumes for which Storage-Level Access Guard has been applied, the UNIX user must map to a Windows user on the SVM that owns the volume.

### Storage-Level Access Guard behavior

- Storage-Level Access Guard applies to all the files or all the directories in a storage object.

Because all files or directories in a volume are subject to Storage-Level Access Guard settings, inheritance

through propagation is not required.

- You can configure Storage-Level Access Guard to apply to files only, to directories only, or to both files and directories within a volume.

- File and directory security

Applies to every directory and file within the storage object. This is the default setting.

- File security

Applies to every file within the storage object. Applying this security does not affect access to, or auditing of, directories.

- Directory security

Applies to every directory within the storage object. Applying this security does not affect access to, or auditing of, files.

- Storage-Level Access Guard is used to restrict permissions.

It will never give extra access permissions.

- If you view the security settings on a file or directory from an NFS or SMB client, you do not see the Storage-Level Access Guard security.

It's applied at the storage object level and stored in the metadata used to determine the effective permissions.

- Storage-level security cannot be revoked from a client, even by a system (Windows or UNIX) administrator.

It is designed to be modified by storage administrators only.

- You can apply Storage-Level Access Guard to volumes with NTFS or mixed security style.
- You can apply Storage-Level Access Guard to volumes with UNIX security style as long as the SVM containing the volume has a CIFS server configured.
- When volumes are mounted under a volume junction path and if Storage-Level Access Guard is present on that path, it will not be propagated to volumes mounted under it.
- The Storage-Level Access Guard security descriptor is replicated with SnapMirror data replication and with SVM replication.
- There is special dispensation for virus scanners.

Exceptional access is allowed to these servers to screen files and directories, even if Storage-Level Access Guard denies access to the object.

- FPolicy notifications are not sent if access is denied because of Storage-Level Access Guard.

## Order of access checks

Access to a file or directory is determined by the combined effect of the export or share permissions, the Storage-Level Access Guard permissions set on volumes, and the native file permissions applied to files and/or directories. All levels of security are evaluated to determine what the effective permissions a file or directory has. The security access checks are performed in the following order:

1. SMB share or NFS export-level permissions
2. Storage-Level Access Guard
3. NTFS file/folder access control lists (ACLs), NFSv4 ACLs, or UNIX mode bits

#### **Use cases for using Storage-Level Access Guard**

Storage-Level Access Guard provides additional security at the storage level, which is not visible from a client side; therefore, it cannot be revoked by any of the users or administrators from their desktops. There are certain use cases where the ability to control access at the storage level is beneficial.

Typical use cases for this feature include the following scenarios:

- Intellectual property protection by auditing and controlling all users' access at the storage level
- Storage for financial services companies, including banking and trading groups
- Government services with separate file storage for individual departments
- Universities protecting all student files

#### **Workflow to configure Storage-Level Access Guard**

The workflow to configure Storage-Level Access Guard (SLAG) uses the same ONTAP CLI commands that you use to configure NTFS file permissions and auditing policies. Instead of configuring file and directory access on a designated target, you configure SLAG on the designated storage virtual machine (SVM) volume.

#### Related information

[Configuring Storage-Level Access Guard](#)

## Configure Storage-Level Access Guard

There are a number of steps you need to follow to configure Storage-Level Access Guard on a volume or qtree. Storage-Level Access Guard provides a level of access security that is set at the storage level. It provides security that applies to all accesses from all NAS protocols to the storage object to which it has been applied.

### Steps

1. Create a security descriptor by using the vserver security file-directory ntfs create command.

```
vserver security file-directory ntfs create -vserver vs1 -ntfs-sd sd1 vserver
security file-directory ntfs show -vserver vs1
```

```
Vserver: vs1
```

| NTFS Security Descriptor Name | Owner Name |
|-------------------------------|------------|
| sd1                           | -          |

A security descriptor is created with the following four default DACL access control entries (ACEs):

```
Vserver: vs1
```

```
NTFS Security Descriptor Name: sd1
```

| Account Name           | Access Type | Access Rights | Apply To                        |
|------------------------|-------------|---------------|---------------------------------|
| BUILTIN\Administrators | allow       | full-control  | this-folder, sub-folders, files |
| BUILTIN\Users          | allow       | full-control  | this-folder, sub-folders, files |
| CREATOR OWNER          | allow       | full-control  | this-folder, sub-folders, files |
| NT AUTHORITY\SYSTEM    | allow       | full-control  | this-folder, sub-folders, files |

If you do not want to use the default entries when configuring Storage-Level Access Guard, you can remove them prior to creating and adding your own ACEs to the security descriptor.

2. Remove any of the default DACL ACEs from the security descriptor that you do not want configured with Storage-Level Access Guard security:
  - a. Remove any unwanted DACL ACEs by using the vserver security file-directory ntfs

`dacl remove` command.

In this example, three default DACL ACEs are removed from the security descriptor: BUILTIN\Administrators, BUILTIN\Users, and CREATOR OWNER.

```
vserver security file-directory ntfs dacl remove -vserver vs1 -ntfs-sd sd1
-access-type allow -account builtin\users vserver security file-directory
ntfs dacl remove -vserver vs1 -ntfs-sd sd1 -access-type allow -account
builtin\administrators vserver security file-directory ntfs dacl remove
-vserver vs1 -ntfs-sd sd1 -access-type allow -account "creator owner"
```

- b. Verify that the DACL ACEs you do not want to use for Storage-Level Access Guard security are removed from the security descriptor by using the `vserver security file-directory ntfs dacl show` command.

In this example, the output from the command verifies that three default DACL ACEs have been removed from the security descriptor, leaving only the NT AUTHORITY\SYSTEM default DACL ACE entry:

```
vserver security file-directory ntfs dacl show -vserver vs1
```

```
Vserver: vs1
NTFS Security Descriptor Name: sd1

Account Name	Access Type	Access Rights	Apply To
NT AUTHORITY\SYSTEM	allow	full-control	this-folder, sub-folders, files

```

3. Add one or more DACL entries to a security descriptor by using the `vserver security file-directory ntfs dacl add` command.

In this example, two DACL ACEs are added to the security descriptor:

```
vserver security file-directory ntfs dacl add -vserver vs1 -ntfs-sd sd1
-access-type allow -account example\engineering -rights full-control -apply-to
this-folder, sub-folders, files vserver security file-directory ntfs dacl add
-vserver vs1 -ntfs-sd sd1 -access-type allow -account "example\Domain Users"
-rights read -apply-to this-folder, sub-folders, files
```

4. Add one or more SACL entries to a security descriptor by using the `vserver security file-directory ntfs sacl add` command.

In this example, two SACL ACEs are added to the security descriptor:

```
vserver security file-directory ntfs sacl add -vserver vs1 -ntfs-sd sd1
-access-type failure -account "example\Domain Users" -rights read -apply-to
this-folder, sub-folders, files vserver security file-directory ntfs sacl add
```

```
-vserver vs1 -ntfs-sd sd1 -access-type success -account example\engineering
-rights full-control -apply-to this-folder,sub-folders,files
```

5. Verify that the DACL and SACL ACEs are configured correctly by using the vserver security file-directory ntfs dacl show and vserver security file-directory ntfs sacl show commands, respectively.

In this example, the following command displays information about DACL entries for security descriptor "sd1":

```
vserver security file-directory ntfs dacl show -vserver vs1 -ntfs-sd sd1
```

```
Vserver: vs1
NTFS Security Descriptor Name: sd1

Account Name Access Access Apply To
 Type Rights
----- ----- -----
EXAMPLE\Domain Users
 allow read this-folder, sub-folders,
files
EXAMPLE\engineering
 allow full-control this-folder, sub-folders,
files
NT AUTHORITY\SYSTEM
 allow full-control this-folder, sub-folders,
files
```

In this example, the following command displays information about SACL entries for security descriptor "sd1":

```
vserver security file-directory ntfs sacl show -vserver vs1 -ntfs-sd sd1
```

```
Vserver: vs1
NTFS Security Descriptor Name: sd1

Account Name Access Access Apply To
 Type Rights
----- ----- -----
EXAMPLE\Domain Users
 failure read this-folder, sub-folders,
files
EXAMPLE\engineering
 success full-control this-folder, sub-folders,
files
```

6. Create a security policy by using the `vserver security file-directory policy create` command.

The following example creates a policy named “policy1”:

```
vserver security file-directory policy create -vserver vs1 -policy-name
policy1
```

7. Verify that the policy is correctly configured by using the `vserver security file-directory policy show` command.

```
vserver security file-directory policy show
```

| Vserver | Policy Name |
|---------|-------------|
| vs1     | policy1     |

8. Add a task with an associated security descriptor to the security policy by using the `vserver security file-directory policy-task add` command with the `-access-control` parameter set to `slag`.

Even though a policy can contain more than one Storage-Level Access Guard task, you cannot configure a policy to contain both file-directory and Storage-Level Access Guard tasks. A policy must contain either all Storage-Level Access Guard tasks or all file-directory tasks.

In this example, a task is added to the policy named “policy1”, which is assigned to security descriptor “sd1”. It is assigned to the `/datavol1` path with the access control type set to “slag”.

```
vserver security file-directory policy task add -vserver vs1 -policy-name
policy1 -path /datavol1 -access-control slag -security-type ntfs -ntfs-mode
propagate -ntfs-sd sd1
```

9. Verify that the task is configured correctly by using the `vserver security file-directory policy task show` command.

```
vserver security file-directory policy task show -vserver vs1 -policy-name
policy1
```

| Vserver: vs1     |       | Policy: policy1 |         |          |           |            |
|------------------|-------|-----------------|---------|----------|-----------|------------|
| Security<br>Name | Index | File/Folder     | Access  | Security | NTFS      | NTFS       |
|                  | Path  |                 | Control | Type     | Mode      | Descriptor |
|                  | 1     | /datavol1       | slag    | ntfs     | propagate | sd1        |

10. Apply the Storage-Level Access Guard security policy by using the vserver security file-directory apply command.

```
vserver security file-directory apply -vserver vs1 -policy-name policy1
```

The job to apply the security policy is scheduled.

11. Verify that the applied Storage-Level Access Guard security settings are correct by using the vserver security file-directory show command.

In this example, the output from the command shows that Storage-Level Access Guard security has been applied to the NTFS volume /datavol1. Even though the default DACL allowing Full Control to Everyone remains, Storage-Level Access Guard security restricts (and audits) access to the groups defined in the Storage-Level Access Guard settings.

```
vserver security file-directory show -vserver vs1 -path /datavol1
```

```

## Effective SLAG matrix

You can configure SLAG on a volume or a qtree or both. The SLAG matrix defines on which volume or qtree is the SLAG configuration applicable under various scenarios listed in the table.

|                                                                           | Volume SLAG in an AFS | Volume SLAG in a Snapshot copy | Qtree SLAG in an AFS | Qtree SLAG in a Snapshot copy |
|---------------------------------------------------------------------------|-----------------------|--------------------------------|----------------------|-------------------------------|
| Volume access in an Access File System (AFS)                              | YES                   | NO                             | N/A                  | N/A                           |
| Volume access in a Snapshot copy                                          | YES                   | NO                             | N/A                  | N/A                           |
| Qtree access in an AFS (when SLAG is present in the qtree)                | NO                    | NO                             | YES                  | NO                            |
| Qtree access in an AFS (when SLAG is not present in qtree)                | YES                   | NO                             | NO                   | NO                            |
| Qtree access in Snapshot copy (when SLAG is present in the qtree AFS)     | NO                    | NO                             | YES                  | NO                            |
| Qtree access in Snapshot copy (when SLAG is not present in the qtree AFS) | YES                   | NO                             | NO                   | NO                            |

## Display Information about Storage-Level Access Guard

Storage-Level Access Guard is a third layer of security applied on a volume or qtree. Storage-Level Access Guard settings cannot be viewed by using the Windows Properties window. You must use the ONTAP CLI to view information about Storage-Level Access Guard security, which you can use to validate your configuration or to troubleshoot file access issues.

### About this task

You must supply the name of the storage virtual machine (SVM) and the path to the volume or qtree whose Storage-Level Access Guard security information you want to display. You can display the output in summary form or as a detailed list.

### Step

1. Display Storage-Level Access Guard security settings with the desired level of detail:

| If you want to display information... | Enter the following command...                                                                               |
|---------------------------------------|--------------------------------------------------------------------------------------------------------------|
| In summary form                       | <code>vserver security file-directory show<br/>-vserver vserver_name -path path</code>                       |
| With expanded detail                  | <code>vserver security file-directory show<br/>-vserver vserver_name -path path<br/>-expand-mask true</code> |

### Examples

The following example displays Storage-Level Access Guard security information for the NTFS security-style volume with the path /datavol1 in SVM vs1:

```

cluster::> vserver security file-directory show -vserver vs1 -path
/datavol1

 Vserver: vs1
 File Path: /datavol1

#### **Remove Storage-Level Access Guard**

You can remove Storage-Level Access Guard on a volume or qtree if you no longer want set access security at the storage level. Removing Storage-Level Access Guard does not modify or remove regular NTFS file and directory security.

#### **Steps**

1. Verify that the volume or qtree has Storage-Level Access Guard configured by using the `vserver security file-directory show` command.

```
vserver security file-directory show -vserver vs1 -path /datavol2
```

```

 Vserver: vs1
 File Path: /datavol2
 File Inode Number: 99

## Manage file access using SMB

### Use local users and groups for authentication and authorization

#### How ONTAP uses local users and groups

#### Local users and groups concepts

You should know what local users and groups are, and some basic information about them, before determining whether to configure and use local users and groups in your environment.

- **Local user**

A user account with a unique security identifier (SID) that has visibility only on the storage virtual machine (SVM) on which it is created. Local user accounts have a set of attributes, including user name and SID. A local user account authenticates locally on the CIFS server using NTLM authentication.

User accounts have several uses:

- Used to grant *User Rights Management* privileges to a user.
- Used to control share-level and file-level access to file and folder resources that the SVM owns.

- **Local group**

A group with a unique SID has visibility only on the SVM on which it is created. Groups contain a set of

members. Members can be local users, domain users, domain groups, and domain machine accounts. Groups can be created, modified, or deleted.

Groups have several uses:

- Used to grant *User Rights Management* privileges to its members.
- Used to control share-level and file-level access to file and folder resources that the SVM owns.

- **Local domain**

A domain that has local scope, which is bounded by the SVM. The local domain's name is the CIFS server name. Local users and groups are contained within the local domain.

- **Security identifier (SID)**

A SID is a variable-length numeric value that identifies Windows-style security principals. For example, a typical SID takes the following form: S-1-5-21-3139654847-1303905135-2517279418-123456.

- **NTLM authentication**

A Microsoft Windows security method used to authenticate users on a CIFS server.

- **Cluster replicated database (RDB)**

A replicated database with an instance on each node in a cluster. Local user and group objects are stored in the RDB.

## Reasons for creating local users and local groups

There are several reasons for creating local users and local groups on your storage virtual machine (SVM). For example, you can access an SMB server by using a local user account if the domain controllers (DCs) are unavailable, you might want to use local groups to assign privileges, or your SMB server is in a workgroup.

You can create one or more local user accounts for the following reasons:

- Your SMB server is in a workgroup, and domain users are not available.  
Local users are required in workgroup configurations.
- You want the ability to authenticate and log in to the SMB server if the domain controllers are unavailable.

Local users can authenticate with the SMB server by using NTLM authentication when the domain controller is down, or when network problems prevent your SMB server from contacting the domain controller.

- You want to assign *User Rights Management* privileges to a local user.

*User Rights Management* is the ability for an SMB server administrator to control what rights the users and groups have on the SVM. You can assign privileges to a user by assigning the privileges to the user's account, or by making the user a member of a local group that has those privileges.

You can create one or more local groups for the following reasons:

- Your SMB server is in a workgroup, and domain groups are not available.

Local groups are not required in workgroup configurations, but they can be useful for managing access privileges for local workgroup users.

- You want to control access to file and folder resources by using local groups for share and file-access control.
- You want to create local groups with customized *User Rights Management* privileges.

Some built-in user groups have predefined privileges. To assign a customized set of privileges, you can create a local group and assign the necessary privileges to that group. You can then add local users, domain users, and domain groups to the local group.

[How local user authentication works](#)

[List of supported privileges](#)

## How local user authentication works

Before a local user can access data on a CIFS server, the user must create an authenticated session.

Because SMB is session-based, the identity of the user can be determined just once, when the session is first set up. The CIFS server uses NTLM-based authentication when authenticating local users. Both NTLMv1 and NTLMv2 are supported.

ONTAP uses local authentication under three use cases. Each use case depends on whether the domain portion of the user name (with the DOMAIN\user format) matches the CIFS server's local domain name (the CIFS server name):

- The domain portion matches

Users who provide local user credentials when requesting access to data are authenticated locally on the CIFS server.

- The domain portion does not match

ONTAP attempts to use NTLM authentication with a domain controller in the domain to which the CIFS server belongs. If authentication succeeds, the login is complete. If it does not succeed, what happens next depends on why authentication did not succeed.

For example, if the user exists in Active Directory but the password is invalid or expired, ONTAP does not attempt to use the corresponding local user account on the CIFS server. Instead, authentication fails. There are other cases where ONTAP uses the corresponding local account on the CIFS server, if it exists, for authentication—even though the NetBIOS domain names do not match. For example, if a matching domain account exists but it is disabled, ONTAP uses the corresponding local account on the CIFS server for authentication.

- The domain portion is not specified

ONTAP first attempts authentication as a local user. If authentication as a local user fails, then ONTAP authenticates the user with a domain controller in the domain to which the CIFS server belongs.

After local or domain user authentication is completed successfully, ONTAP constructs a complete user access token, which takes into account local group membership and privileges.

For more information about NTLM authentication for local users, see the Microsoft Windows documentation.

## Related information

[Enabling or disabling local user authentication](#)

## How user access tokens are constructed

When a user maps a share, an authenticated SMB session is established and a user access token is constructed that contains information about the user, the user's group membership and cumulative privileges, and the mapped UNIX user.

Unless the functionality is disabled, local user and group information is also added to the user access token. The way access tokens are constructed depends on whether the login is for a local user or an Active Directory domain user:

- Local user login

Although local users can be members of different local groups, local groups cannot be members of other local groups. The local user access token is composed of a union of all privileges assigned to groups to which a particular local user is a member.

- Domain user login

When a domain user logs in, ONTAP obtains a user access token that contains the user SID and SIDs for all the domain groups to which the user is a member. ONTAP uses the union of the domain user access token with the access token provided by local memberships of the user's domain groups (if any), as well as any direct privileges assigned to the domain user or any of its domain group memberships.

For both local and domain user login, the Primary Group RID is also set for the user access token. The default RID is `Domain Users (RID 513)`. You cannot change the default.

The Windows-to-UNIX and UNIX-to-Windows name mapping process follows the same rules for both local and domain accounts.

There is no implied, automatic mapping from a UNIX user to a local account. If this is required, an explicit mapping rule must be specified using the existing name mapping commands.

## Guidelines for using SnapMirror on SVMs that contain local groups

You should be aware of the guidelines when you configure SnapMirror on volumes owned by SVMs that contain local groups.

You cannot use local groups in ACEs applied to files, directories, or shares that are replicated by SnapMirror to another SVM. If you use the SnapMirror feature to create a DR mirror to a volume on another SVM and the volume has an ACE for a local group, the ACE is not valid on the mirror. If data is replicated to a different SVM, the data is effectively crossing into a different local domain. The permissions granted to local users and groups are valid only within the scope of the SVM on which they were originally created.

## **What happens to local users and groups when deleting CIFS servers**

The default set of local users and groups is created when a CIFS server is created, and they are associated with the storage virtual machine (SVM) hosting the CIFS server. SVM administrators can create local users and groups at any time. You need to be aware of what happens to local users and groups when you delete the CIFS server.

Local users and groups are associated with SVMs; therefore, they are not deleted when CIFS servers are deleted due to security considerations. Although local users and groups are not deleted when the CIFS server is deleted, they are hidden. You cannot view or manage local users and groups until you re-create a CIFS server on the SVM.

The CIFS server administrative status does not affect visibility of local users or groups.

## **How you can use Microsoft Management Console with local users and groups**

You can view information about local users and groups from the Microsoft Management Console. With this release of ONTAP, you cannot perform other management tasks for local users and groups from the Microsoft Management Console.

## **Guidelines for reverting**

If you plan to revert the cluster to an ONTAP release that does not support local users and groups and local users and groups are being used to manage file access or user rights, you must be aware of certain considerations.

- Due to security reasons, information about configured local users, groups, and privileges are not deleted when ONTAP is reverted to a version that does not support local users and groups functionality.
- Upon a revert to a prior major version of ONTAP, ONTAP does not use local users and groups during authentication and credential creation.
- Local users and groups are not removed from file and folder ACLs.
- File access requests that depend on access being granted because of permissions granted to local users or groups are denied.

To allow access, you must reconfigure file permissions to allow access based on domain objects instead of local user and group objects.

## **What local privileges are**

### **List of supported privileges**

ONTAP has a predefined set of supported privileges. Certain predefined local groups have some of these privileges added to them by default. You can also add or remove privileges from the predefined groups or create new local users or groups and add privileges to the groups that you created or to existing domain users and groups.

The following table lists the supported privileges on the storage virtual machine (SVM) and provides a list of BUILTIN groups with assigned privileges:

| Privilege name           | Default security setting                                                                                | Description                                                                                                                                      |
|--------------------------|---------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------|
| SeTcbPrivilege           | None                                                                                                    | Act as part of the operating system                                                                                                              |
| SeBackupPrivilege        | BUILTIN\Administrators,<br>BUILTIN\Backup Operators                                                     | Back up files and directories, overriding any ACLs                                                                                               |
| SeRestorePrivilege       | BUILTIN\Administrators,<br>BUILTIN\Backup Operators                                                     | Restore files and directories, overriding any ACLs Set any valid user or group SID as the file owner                                             |
| SeTakeOwnershipPrivilege | BUILTIN\Administrators                                                                                  | Take ownership of files or other objects                                                                                                         |
| SeSecurityPrivilege      | BUILTIN\Administrators                                                                                  | Manage auditingThis includes viewing, dumping, and clearing the security log.                                                                    |
| SeChangeNotifyPrivilege  | BUILTIN\Administrators,<br>BUILTIN\Backup Operators,<br>BUILTIN\Power Users,<br>BUILTIN\Users, Everyone | Bypass traverse checkingUsers with this privilege are not required to have traverse (x) permissions to traverse folders, symlinks, or junctions. |

## Related information

- [Assign local privileges](#)

## Assign privileges

You can assign privileges directly to local users or domain users. Alternatively, you can assign users to local groups whose assigned privileges match the capabilities that you want those users to have.

- You can assign a set of privileges to a group that you create.

You then add a user to the group that has the privileges that you want that user to have.

- You can also assign local users and domain users to predefined groups whose default privileges match the privileges that you want to grant to those users.

## Related information

- [Resetting privileges for local or domain users and groups](#)
- [Configuring bypass traverse checking](#)

## **Guidelines for using BUILTIN groups and the local administrator account**

There are certain guidelines you should keep in mind when you use BUILTIN groups and the local administrator account. For example, you can rename the local administrator account, but you cannot delete this account.

- The Administrator account can be renamed but cannot be deleted.
- The Administrator account cannot be removed from the BUILTIN\Administrators group.
- BUILTIN groups can be renamed but cannot be deleted.

After the BUILTIN group is renamed, another local object can be created with the well-known name; however, the object is assigned a new RID.

- There is no local Guest account.

## **Related information**

[Predefined BUILTIN groups and default privileges](#)

## **Requirements for local user passwords**

By default, local user passwords must meet complexity requirements. The password complexity requirements are similar to the requirements defined in the Microsoft Windows *Local security policy*.

The password must meet the following criteria:

- Must be at least six characters in length
- Must not contain the user account name
- Must contain characters from at least three of the following four categories:
  - English uppercase characters (A through Z)
  - English lowercase characters (a through z)
  - Base 10 digits (0 through 9)
  - Special characters:  
~ ! @ # \$ % ^ & \* \_ - + = ` \| ()[]:; " ' < > , . ? /

## **Related information**

## **Predefined BUILTIN groups and default privileges**

You can assign membership of a local user or domain user to a predefined set of BUILTIN groups provided by ONTAP. Predefined groups have predefined privileges assigned.

The following table describes the predefined groups:

| Predefined BUILTIN group                                                                                                                                                                                                                                                                                                                                                | Default privileges                                                                                                                                                                                  |

## Related information

[Guidelines for using BUILTIN groups and the local administrator account](#)

[List of supported privileges](#)

[Configuring bypass traverse checking](#)

[Enable or disable local users and groups functionality](#)

## **Enable or disable local users and groups functionality overview**

Before you can use local users and groups for access control of NTFS security-style data, local user and group functionality must be enabled. Additionally, if you want to use local users for SMB authentication, the local user authentication functionality must be enabled.

Local users and groups functionality and local user authentication are enabled by default. If they are not enabled, you must enable them before you can configure and use local users and groups. You can disable local users and groups functionality at any time.

In addition to explicitly disabling local user and group functionality, ONTAP disables local user and group functionality if any node in the cluster is reverted to an ONTAP release that does not support the functionality. Local user and group functionality is not enabled until all nodes in the cluster are running a version of ONTAP that supports it.

### **Related information**

[Modify local user accounts](#)

[Add privileges to local or domain users or groups](#)

## **Enable or disable local users and groups**

You can enable or disable local users and groups for SMB access on storage virtual machines (SVMs). Local users and groups functionality is enabled by default.

### **About this task**

You can use local users and groups when configuring SMB share and NTFS file permissions and can optionally use local users for authentication when creating an SMB connection. To use local users for authentication, you must also enable the local users and groups authentication option.

### **Steps**

1. Set the privilege level to advanced: `set -privilege advanced`
2. Perform one of the following actions:

| <b>If you want local users and groups to be...</b> | <b>Enter the command...</b>                                                                            |
|----------------------------------------------------|--------------------------------------------------------------------------------------------------------|
| Enabled                                            | <code>vserver cifs options modify -vserver vserver_name -is-local-users-and-groups-enabled true</code> |

| If you want local users and groups to be... | Enter the command...                                                                              |
|---------------------------------------------|---------------------------------------------------------------------------------------------------|
| Disabled                                    | vserver cifs options modify -vserver <i>vserver_name</i> -is-local-users-and-groups-enabled false |

3. Return to the admin privilege level: `set -privilege admin`

### Example

The following example enables local users and groups functionality on SVM vs1:

```
cluster1::> set -privilege advanced
Warning: These advanced commands are potentially dangerous; use them
only when directed to do so by technical support personnel.
Do you wish to continue? (y or n): y

cluster1::*> vserver cifs options modify -vserver vs1 -is-local-users-and
-groups-enabled true

cluster1::*> set -privilege admin
```

### Related information

[Enable or disable local user authentication](#)

[Enable or disable local user accounts](#)

### Enable or disable local user authentication

You can enable or disable local user authentication for SMB access on storage virtual machines (SVMs). The default is to allow local user authentication, which is useful when the SVM cannot contact a domain controller or if you choose not to use domain-level access controls.

#### Before you begin

Local users and groups functionality must be enabled on the CIFS server.

#### About this task

You can enable or disable local user authentication at any time. If you want to use local users for authentication when creating an SMB connection, you must also enable the CIFS server's local users and groups option.

#### Steps

1. Set the privilege level to advanced: `set -privilege advanced`
2. Perform one of the following actions:

| If you want local authentication to be... | Enter the command...                                                                  |
|-------------------------------------------|---------------------------------------------------------------------------------------|
| Enabled                                   | vserver cifs options modify -vserver <i>vserver_name</i> -is-local-auth-enabled true  |
| Disabled                                  | vserver cifs options modify -vserver <i>vserver_name</i> -is-local-auth-enabled false |

3. Return to the admin privilege level: `set -privilege admin`

### Example

The following example enables local user authentication on SVM vs1:

```
cluster1::> set -privilege advanced
Warning: These advanced commands are potentially dangerous; use them
only when directed to do so by technical support personnel.
Do you wish to continue? (y or n): y

cluster1::*> vserver cifs options modify -vserver vs1 -is-local-auth
-enabled true

cluster1::*> set -privilege admin
```

### Related information

[How local user authentication works](#)

[Enabling or disabling local users and groups](#)

[Manage local user accounts](#)

[Modify local user accounts](#)

You can modify a local user account if you want to change an existing user's full name or description, and if you want to enable or disable the user account. You can also rename a local user account if the user's name is compromised or if a name change is needed for administrative purposes.

| If you want to...                 | Enter the command...                                                                                                                                                                                                                    |
|-----------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Modify the local user's full name | <code>vserver cifs users-and-groups local-user modify -vserver <i>vserver_name</i> -user-name <i>user_name</i> -full-name <i>text</i></code> If the full name contains a space, then it must be enclosed within double quotation marks. |

| If you want to...                        | Enter the command...                                                                                                                                                                                                                                              |
|------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Modify the local user's description      | vserver cifs users-and-groups local-user modify -vserver <i>vserver_name</i> -user-name <i>user_name</i> -description <i>text</i> If the description contains a space, then it must be enclosed within double quotation marks.                                    |
| Enable or disable the local user account | vserver cifs users-and-groups local-user modify -vserver <i>vserver_name</i> -user-name <i>user_name</i> -is-account-disabled {true false}                                                                                                                        |
| Rename the local user account            | vserver cifs users-and-groups local-user rename -vserver <i>vserver_name</i> -user-name <i>user_name</i> -new-user-name <i>new_user_name</i> When renaming a local user, the new user name must remain associated with the same CIFS server as the old user name. |

### Example

The following example renames the local user “CIFS\_SERVER\sue” to “CIFS\_SERVER\sue\_new” on storage virtual machine (SVM, formerly known as Vserver) vs1:

```
cluster1::> vserver cifs users-and-groups local-user rename -user-name
CIFS_SERVER\sue -new-user-name CIFS_SERVER\sue_new -vserver vs1
```

### Enable or disable local user accounts

You enable a local user account if you want the user to be able to access data contained in the storage virtual machine (SVM) over an SMB connection. You can also disable a local user account if you do not want that user to access SVM data over SMB.

#### About this task

You enable a local user by modifying the user account.

#### Step

1. Perform the appropriate action:

| If you want to...       | Enter the command...                                                                                                                |
|-------------------------|-------------------------------------------------------------------------------------------------------------------------------------|
| Enable the user account | vserver cifs users-and-groups local-user modify -vserver <i>vserver_name</i> -user-name <i>user_name</i> -is-account-disabled false |

| If you want to...        | Enter the command...                                                                                                                |
|--------------------------|-------------------------------------------------------------------------------------------------------------------------------------|
| Disable the user account | vserver cifs users-and-groups local-user modify -vserver <i>vserver_name</i> -user-name <i>user_name</i> -is-account -disabled true |

## Change local user account passwords

You can change a local user's account password. This can be useful if the user's password is compromised or if the user has forgotten the password.

### Step

1. Change the password by performing the appropriate action: `vserver cifs users-and-groups local-user set-password -vserver vserver_name -user-name user_name`

### Example

The following example sets the password for the local user "CIFS\_SERVER\sue" associated with storage virtual machine (SVM, formerly known as Vserver) vs1:

```
cluster1::> vserver cifs users-and-groups local-user set-password -user-name CIFS_SERVER\sue -vserver vs1
```

Enter the new password:

Confirm the new password:

### Related information

[Enabling or disabling required password complexity for local SMB users](#)

### Display information about local users

You can display a list of all local users in a summary form. If you want to determine which account settings are configured for a specific user, you can display detailed account information for that user as well as the account information for multiple users. This information can help you determine if you need to modify a user's settings, and also to troubleshoot authentication or file access issues.

### About this task

Information about a user's password is never displayed.

### Step

1. Perform one of the following actions:

| If you want to...                                                        | Enter the command...                                                                                             |
|--------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------|
| Display information about all users on the storage virtual machine (SVM) | vserver cifs users-and-groups local-user show -vserver <i>vserver_name</i>                                       |
| Display detailed account information for a user                          | vserver cifs users-and-groups local-user show -instance -vserver <i>vserver_name</i> -user-name <i>user_name</i> |

There are other optional parameters that you can choose when you run the command. See the man page for more information.

### Example

The following example displays information about all local users on SVM vs1:

```
cluster1::> vserver cifs users-and-groups local-user show -vserver vs1
Vserver User Name Full Name Description
----- -----
vs1 CIFS_SERVER\Administrator James Smith Built-in administrator
account
vs1 CIFS_SERVER\sue Sue Jones
```

### Display information about group memberships for local users

You can display information about which local groups that a local user belongs to. You can use this information to determine what access the user should have to files and folders. This information can be useful in determining what access rights the user should have to files and folders or when troubleshooting file access issues.

#### About this task

You can customize the command to display only the information that you want to see.

#### Step

1. Perform one of the following actions:

| If you want to...                                                                                  | Enter the command...                                                                   |
|----------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------|
| Display local user membership information for a specified local user                               | vserver cifs users-and-groups local-user show-membership -user-name <i>user_name</i>   |
| Display local user membership information for the local group of which this local user is a member | vserver cifs users-and-groups local-user show-membership -membership <i>group_name</i> |

| If you want to...                                                                                                      | Enter the command...                                                                            |
|------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------|
| Display user membership information for local users that are associated with a specified storage virtual machine (SVM) | vserver cifs users-and-groups local-user show-membership -vserver <i>vserver_name</i>           |
| Display detailed information for all local users on a specified SVM                                                    | vserver cifs users-and-groups local-user show-membership -instance -vserver <i>vserver_name</i> |

### Example

The following example displays the membership information for all local users on SVM vs1; user “CIFS\_SERVER\Administrator” is a member of the “BUILTIN\Administrators” group, and “CIFS\_SERVER\sue” is a member of “CIFS\_SERVER\g1” group:

```
cluster1::> vserver cifs users-and-groups local-user show-membership
-vserver vs1
Vserver User Name Membership

vs1 CIFS_SERVER\Administrator BUILTIN\Administrators
 CIFS_SERVER\sue CIFS_SERVER\g1
```

### Delete local user accounts

You can delete local user accounts from your storage virtual machine (SVM) if they are no longer needed for local SMB authentication to the CIFS server or for determining access rights to data contained on your SVM.

#### About this task

Keep the following in mind when deleting local users:

- The file system is not altered.

Windows Security Descriptors on files and directories that refer to this user are not adjusted.

- All references to local users are removed from the membership and privileges databases.
- Standard, well-known users such as Administrator cannot be deleted.

#### Steps

1. Determine the name of the local user account that you want to delete: `vserver cifs users-and-groups local-user show -vserver vserver_name`
2. Delete the local user: `vserver cifs users-and-groups local-user delete -vserver vserver_name -user-name username_name`
3. Verify that the user account is deleted: `vserver cifs users-and-groups local-user show -vserver vserver_name`

## Example

The following example deletes the local user “CIFS\_SERVER\sue” associated with SVM vs1:

```
cluster1::> vserver cifs users-and-groups local-user show -vserver vs1
Vserver User Name Full Name Description

vs1 CIFS_SERVER\Administrator James Smith Built-in administrator
account
vs1 CIFS_SERVER\sue Sue Jones

cluster1::> vserver cifs users-and-groups local-user delete -vserver vs1
-user-name CIFS_SERVER\sue

cluster1::> vserver cifs users-and-groups local-user show -vserver vs1
Vserver User Name Full Name Description

vs1 CIFS_SERVER\Administrator James Smith Built-in administrator
account
```

## Manage local groups

### Modify local groups

You can modify existing local groups by changing the description for an existing local group or by renaming the group.

| If you want to...                  | Use the command...                                                                                                                                                                                                                |
|------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Modify the local group description | vserver cifs users-and-groups local-group modify -vserver <i>vserver_name</i> -group-name <i>group_name</i> -description <i>text</i> If the description contains a space, then it must be enclosed within double quotation marks. |
| Rename the local group             | vserver cifs users-and-groups local-group rename -vserver <i>vserver_name</i> -group-name <i>group_name</i> -new-group-name <i>new_group_name</i>                                                                                 |

## Examples

The following example renames the local group “CIFS\_SERVER\engineering” to “CIFS\_SERVER\engineering\_new”:

```
cluster1::> vserver cifs users-and-groups local-group rename -vserver vs1
-group-name CIFS_SERVER\engineering -new-group-name
CIFS_SERVER\engineering_new
```

The following example modifies the description of the local group “CIFS\_SERVER\engineering”:

```
cluster1::> vserver cifs users-and-groups local-group modify -vserver vs1
-group-name CIFS_SERVER\engineering -description "New Description"
```

### Display information about local groups

You can display a list of all local groups configured on the cluster or on a specified storage virtual machine (SVM). This information can be useful when troubleshooting file-access issues to data contained on the SVM or user-rights (privilege) issues on the SVM.

#### Step

1. Perform one of the following actions:

| If you want information about... | Enter the command...                                                        |
|----------------------------------|-----------------------------------------------------------------------------|
| All local groups on the cluster  | vserver cifs users-and-groups local-group show                              |
| All local groups on the SVM      | vserver cifs users-and-groups local-group show -vserver <i>vserver_name</i> |

There are other optional parameters that you can choose when you run this command. See the man page for more information.

#### Example

The following example displays information about all local groups on SVM vs1:

```
cluster1::> vserver cifs users-and-groups local-group show -vserver vs1
Vserver Group Name Description
----- -----
vs1 BUILTIN\Administrators Built-in Administrators group
vs1 BUILTIN\Backup Operators Backup Operators group
vs1 BUILTIN\Power Users Restricted administrative privileges
vs1 BUILTIN\Users All users
vs1 CIFS_SERVER\engineering
vs1 CIFS_SERVER\sales
```

## Manage local group membership

You can manage local group membership by adding and removing local or domain users, or adding and removing domain groups. This is useful if you want to control access to data based on access controls placed on the group or if you want users to have privileges associated with that group.

### About this task

Guidelines for adding members to a local group:

- You cannot add users to the special *Everyone* group.
- The local group must exist before you can add a user to it.
- The user must exist before you can add the user to a local group.
- You cannot add a local group to another local group.
- To add a domain user or group to a local group, Data ONTAP must be able to resolve the name to a SID.

Guidelines for removing members from a local group:

- You cannot remove members from the special *Everyone* group.
- The group from which you want to remove a member must exist.
- ONTAP must be able to resolve the names of members that you want to remove from the group to a corresponding SID.

### Step

1. Add or remove a member in a group.

| If you want to...            | Then use the command...                                                                                                                                                                                                                                                              |
|------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Add a member to a group      | <pre>vserver cifs users-and-groups local-group add-members -vserver _vserver_name_ -group-name _group_name_ -member-names name[,...]</pre> <p>You can specify a comma-delimited list of local users, domain users, or domain groups to add to the specified local group.</p>         |
| Remove a member from a group | <pre>vserver cifs users-and-groups local-group remove-members -vserver _vserver_name_ -group-name _group_name_ -member-names name[,...]</pre> <p>You can specify a comma-delimited list of local users, domain users, or domain groups to remove from the specified local group.</p> |

The following example adds a local user “SMB\_SERVER\ sue” and a domain group “AD\_DOM\dom\_eng” to the local group “SMB\_SERVER\engineering” on SVM vs1:

```
cluster1::> vserver cifs users-and-groups local-group add-members
-vserver vs1 -group-name SMB_SERVER\engineering -member-names
SMB_SERVER\sue,AD_DOMAIN\dom_eng
```

The following example removes the local users “SMB\_SERVER\sue” and “SMB\_SERVER\james” from the local group “SMB\_SERVER\engineering” on SVM vs1:

```
cluster1::> vserver cifs users-and-groups local-group remove-members
-vserver vs1 -group-name SMB_SERVER\engineering -member-names
SMB_SERVER\sue,SMB_SERVER\james
```

## Related information

[Displaying information about members of local groups](#)

## Display information about members of local groups

You can display a list of all members of local groups configured on the cluster or on a specified storage virtual machine (SVM). This information can be useful when troubleshooting file-access issues or user-rights (privilege) issues.

### Step

1. Perform one of the following actions:

| If you want to display information about... | Enter the command...                                                                   |
|---------------------------------------------|----------------------------------------------------------------------------------------|
| Members of all local groups on the cluster  | vserver cifs users-and-groups local-group show-members                                 |
| Members of all local groups on the SVM      | vserver cifs users-and-groups local-group show-members -vserver<br><i>vserver_name</i> |

### Example

The following example displays information about members of all local groups on SVM vs1:

```

cluster1::> vserver cifs users-and-groups local-group show-members
-vserver vs1
Vserver Group Name Members

vs1 BUILTIN\Administrators CIFS_SERVER\Administrator
 AD_DOMAIN\Domain Admins
 AD_DOMAIN\dom_grp1
 AD_DOMAIN\Domain Users
 AD_DOMAIN\dom_usr1
 CIFS_SERVER\james
 BUILTIN\Users
 CIFS_SERVER\engineering

```

## Delete a local group

You can delete a local group from the storage virtual machine (SVM) if it is no longer needed for determining access rights to data associated with that SVM or if it is no longer needed for assigning SVM user rights (privileges) to group members.

### About this task

Keep the following in mind when deleting local groups:

- The file system is not altered.

Windows Security Descriptors on files and directories that refer to this group are not adjusted.

- If the group does not exist, an error is returned.
- The special *Everyone* group cannot be deleted.
- Built-in groups such as *BUILTIN\Administrators* *BUILTIN\Users* cannot be deleted.

### Steps

1. Determine the name of the local group that you want to delete by displaying the list of local groups on the SVM: `vserver cifs users-and-groups local-group show -vserver vserver_name`
2. Delete the local group: `vserver cifs users-and-groups local-group delete -vserver vserver_name -group-name group_name`
3. Verify that the group is deleted: `vserver cifs users-and-groups local-user show -vserver vserver_name`

### Example

The following example deletes the local group “CIFS\_SERVER\sales” associated with SVM vs1:

```

cluster1::> vserver cifs users-and-groups local-group show -vserver vs1
Vserver Group Name Description
----- -----
vs1 BUILTIN\Administrators Built-in Administrators group
vs1 BUILTIN\Backup Operators Backup Operators group
vs1 BUILTIN\Power Users Restricted administrative
privileges
vs1 BUILTIN\Users All users
vs1 CIFS_SERVER\engineering
vs1 CIFS_SERVER\sales

```

```

cluster1::> vserver cifs users-and-groups local-group delete -vserver vs1
-group-name CIFS_SERVER\sales

```

```

cluster1::> vserver cifs users-and-groups local-group show -vserver vs1
Vserver Group Name Description
----- -----
vs1 BUILTIN\Administrators Built-in Administrators group
vs1 BUILTIN\Backup Operators Backup Operators group
vs1 BUILTIN\Power Users Restricted administrative
privileges
vs1 BUILTIN\Users All users
vs1 CIFS_SERVER\engineering

```

## **Update domain user and group names in local databases**

You can add domain users and groups to a CIFS server's local groups. These domain objects are registered in local databases on the cluster. If a domain object is renamed, the local databases must be manually updated.

### **About this task**

You must specify the name of the storage virtual machine (SVM) on which you want to update domain names.

### **Steps**

1. Set the privilege level to advanced: `set -privilege advanced`
2. Perform the appropriate action:

| If you want to update domain users and groups and...                                | Use this command...                                                           |
|-------------------------------------------------------------------------------------|-------------------------------------------------------------------------------|
| Display domain users and groups that successfully updated and that failed to update | <code>vserver cifs users-and-groups update-names -vserver vserver_name</code> |

| If you want to update domain users and groups and...         | Use this command...                                                                                       |
|--------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------|
| Display domain users and groups that successfully updated    | <code>vserver cifs users-and-groups update-names -vserver vserver_name -display -failed-only false</code> |
| Display only the domain users and groups that fail to update | <code>vserver cifs users-and-groups update-names -vserver vserver_name -display -failed-only true</code>  |
| Suppress all status information about updates                | <code>vserver cifs users-and-groups update-names -vserver vserver_name -suppress-all-output true</code>   |

3. Return to the admin privilege level: `set -privilege admin`

#### Example

The following example updates the names of domain users and groups associated with storage virtual machine (SVM, formerly known as Vserver) vs1. For the last update, there is a dependent chain of names that needs to be updated:

```

cluster1::> set -privilege advanced
Warning: These advanced commands are potentially dangerous; use them
only when directed to do so by technical support personnel.
Do you wish to continue? (y or n): y

cluster1::*> vserver cifs users-and-groups update-names -vserver vs1

Vserver: vs1
SID: S-1-5-21-123456789-234565432-987654321-12345
Domain: EXAMPLE1
Out-of-date Name: dom_user1
Updated Name: dom_user2
Status: Successfully updated

Vserver: vs1
SID: S-1-5-21-123456789-234565432-987654322-23456
Domain: EXAMPLE2
Out-of-date Name: dom_user1
Updated Name: dom_user2
Status: Successfully updated

Vserver: vs1
SID: S-1-5-21-123456789-234565432-987654321-123456
Domain: EXAMPLE1
Out-of-date Name: dom_user3
Updated Name: dom_user4
Status: Successfully updated; also updated SID "S-1-5-21-
123456789-234565432-987654321-123457"
 to name "dom_user5"; also updated SID "S-1-5-21-
123456789-234565432-987654321-123458"
 to name "dom_user6"; also updated SID "S-1-5-21-
123456789-234565432-987654321-123459"
 to name "dom_user7"; also updated SID "S-1-5-21-
123456789-234565432-987654321-123460"
 to name "dom_user8"

```

The command completed successfully. 7 Active Directory objects have been updated.

```
cluster1::*> set -privilege admin
```

## Manage local privileges

## Add privileges to local or domain users or groups

You can manage user rights for local or domain users or groups by adding privileges. The added privileges override the default privileges assigned to any of these objects. This provides enhanced security by allowing you to customize what privileges a user or group has.

### Before you begin

The local or domain user or group to which privileges will be added must already exist.

### About this task

Adding a privilege to an object overrides the default privileges for that user or group. Adding a privilege does not remove previously added privileges.

You must keep the following in mind when adding privileges to local or domain users or groups:

- You can add one or more privileges.
- When adding privileges to a domain user or group, ONTAP might validate the domain user or group by contacting the domain controller.

The command might fail if ONTAP is unable to contact the domain controller.

### Steps

1. Add one or more privileges to a local or domain user or group: `vserver cifs users-and-groups privilege add-privilege -vserver _vserver_name_ -user-or-group-name name -privileges _privilege_[,...]`
2. Verify that the desired privileges are applied to the object: `vserver cifs users-and-groups privilege show -vserver vserver_name -user-or-group-name name`

### Example

The following example adds the privileges “SeTcbPrivilege” and “SeTakeOwnershipPrivilege” to the user “CIFS\_SERVER\sue” on storage virtual machine (SVM, formerly known as Vserver) vs1:

```
cluster1::> vserver cifs users-and-groups privilege add-privilege -vserver vs1 -user-or-group-name CIFS_SERVER\sue -privileges SeTcbPrivilege,SeTakeOwnershipPrivilege

cluster1::> vserver cifs users-and-groups privilege show -vserver vs1
Vserver User or Group Name Privileges
----- -----
vs1 CIFS_SERVER\sue SeTcbPrivilege
 SeTakeOwnershipPrivilege
```

## Remove privileges from local or domain users or groups

You can manage user rights for local or domain users or groups by removing privileges. This provides enhanced security by allowing you to customize the maximum privileges

that users and groups have.

### Before you begin

The local or domain user or group from which privileges will be removed must already exist.

### About this task

You must keep the following in mind when removing privileges from local or domain users or groups:

- You can remove one or more privileges.
- When removing privileges from a domain user or group, ONTAP might validate the domain user or group by contacting the domain controller.

The command might fail if ONTAP is unable to contact the domain controller.

### Steps

1. Remove one or more privileges from a local or domain user or group: `vserver cifs users-and-groups privilege remove-privilege -vserver _vserver_name_ -user-or-group-name _name_ -privileges _privilege_[,...]`
2. Verify that the desired privileges have been removed from the object: `vserver cifs users-and-groups privilege show -vserver vserver_name -user-or-group-name name`

### Example

The following example removes the privileges “SeTcbPrivilege” and “SeTakeOwnershipPrivilege” from the user “CIFS\_SERVER\sue” on storage virtual machine (SVM, formerly known as Vserver) vs1:

```
cluster1::> vserver cifs users-and-groups privilege show -vserver vs1
Vserver User or Group Name Privileges

vs1 CIFS_SERVER\sue SeTcbPrivilege
 SeTakeOwnershipPrivilege

cluster1::> vserver cifs users-and-groups privilege remove-privilege
-vserver vs1 -user-or-group-name CIFS_SERVER\sue -privileges
SeTcbPrivilege,SeTakeOwnershipPrivilege

cluster1::> vserver cifs users-and-groups privilege show -vserver vs1
Vserver User or Group Name Privileges

vs1 CIFS_SERVER\sue -
```

### Reset privileges for local or domain users and groups

You can reset privileges for local or domain users and groups. This can be useful when you have made modifications to privileges for a local or domain user or group and those modifications are no longer wanted or needed.

### About this task

Resetting privileges for a local or domain user or group removes any privilege entries for that object.

## Steps

1. Reset the privileges on a local or domain user or group: vserver cifs users-and-groups privilege reset-privilege -vserver *vserver\_name* -user-or-group-name *name*
2. Verify that the privileges are reset on the object: vserver cifs users-and-groups privilege show -vserver *vserver\_name* -user-or-group-name *name*

## Examples

The following example resets the privileges on the user “CIFS\_SERVER\sue” on storage virtual machine (SVM, formerly known as Vserver) vs1. By default, normal users do not have privileges associated with their accounts:

```
cluster1::> vserver cifs users-and-groups privilege show
Vserver User or Group Name Privileges

vs1 CIFS_SERVER\sue SeTcbPrivilege
 SeTakeOwnershipPrivilege

cluster1::> vserver cifs users-and-groups privilege reset-privilege
-vserver vs1 -user-or-group-name CIFS_SERVER\sue

cluster1::> vserver cifs users-and-groups privilege show
This table is currently empty.
```

The following example resets the privileges for the group “BUILTIN\Administrators”, effectively removing the privilege entry:

```
cluster1::> vserver cifs users-and-groups privilege show
Vserver User or Group Name Privileges

vs1 BUILTIN\Administrators SeRestorePrivilege
 SeSecurityPrivilege
 SeTakeOwnershipPrivilege

cluster1::> vserver cifs users-and-groups privilege reset-privilege
-vserver vs1 -user-or-group-name BUILTIN\Administrators

cluster1::> vserver cifs users-and-groups privilege show
This table is currently empty.
```

## Display information about privilege overrides

You can display information about custom privileges assigned to domain or local user accounts or groups. This information helps you determine whether the desired user rights

are applied.

## Step

1. Perform one of the following actions:

| If you want to display information about...                                                      | Enter this command...                                                                       |
|--------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------|
| Custom privileges for all domain and local users and groups on the storage virtual machine (SVM) | vserver cifs users-and-groups privilege show -vserver vserver_name                          |
| Custom privileges for a specific domain or local user and group on the SVM                       | vserver cifs users-and-groups privilege show -vserver vserver_name -user-or-group-name name |

There are other optional parameters that you can choose when you run this command. See the man page for more information.

## Example

The following command displays all privileges explicitly associated with local or domain users and groups for SVM vs1:

```
cluster1::> vserver cifs users-and-groups privilege show -vserver vs1
Vserver User or Group Name Privileges

vs1 BUILTIN\Administrators SeTakeOwnershipPrivilege
 SeRestorePrivilege
vs1 CIFS_SERVER\sue SeTcbPrivilege
 SeTakeOwnershipPrivilege
```

## Configure bypass traverse checking

### Configure bypass traverse checking overview

Bypass traverse checking is a user right (also known as a *privilege*) that determines whether a user can traverse all the directories in the path to a file even if the user does not have permissions on the traversed directory. You should understand what happens when allowing or disallowing bypass traverse checking, and how to configure bypass traverse checking for users on storage virtual machines (SVMs).

### What happens when allowing or disallowing bypass traverse checking

- If allowed, when a user attempts to access a file, ONTAP does not check the traverse permission for the intermediate directories when determining whether to grant or deny access to the file.
- If disallowed, ONTAP checks the traverse (execute) permission for all directories in the path to the file.

If any of the intermediate directories do not have the “X” (traverse permission), ONTAP denies access to the file.

## Configure bypass traverse checking

You can configure bypass traverse checking by using the ONTAP CLI or by configuring Active Directory group policies with this user right.

The `SeChangeNotifyPrivilege` privilege controls whether users are allowed to bypass traverse checking.

- Adding it to local SMB users or groups on the SVM or to domain users or groups allows bypass traverse checking.
- Removing it from local SMB users or groups on the SVM or from domain users or groups disallows bypass traverse checking.

By default, the following BUILTIN groups on the SVM have the right to bypass traverse checking:

- BUILTIN\Administrators
- BUILTIN\Power Users
- BUILTIN\Backup Operators
- BUILTIN\Users
- Everyone

If you do not want to allow members of one of these groups to bypass traverse checking, you must remove this privilege from the group.

You must keep the following in mind when configuring bypass traverse checking for local SMB users and groups on the SVM by using the CLI:

- If you want to allow members of a custom local or domain group to bypass traverse checking, you must add the `SeChangeNotifyPrivilege` privilege to that group.
- If you want to allow an individual local or domain user to bypass traverse checking and that user is not a member of a group with that privilege, you can add the `SeChangeNotifyPrivilege` privilege to that user account.
- You can disable bypass traverse checking for local or domain users or groups by removing the `SeChangeNotifyPrivilege` privilege at any time.

To disable bypass travers checking for specified local or domain users or groups, you must also remove the `SeChangeNotifyPrivilege` privilege from the `Everyone` group.

## Related information

## Add privileges to local or domain users or groups

### Allow users or groups to bypass directory traverse checking

If you want a user to be able traverse all the directories in the path to a file even if the user does not have permissions on a traversed directory, you can add the SeChangeNotifyPrivilege privilege to local SMB users or groups on storage virtual machines (SVMs). By default, users are able to bypass directory traverse checking.

#### Before you begin

- A SMB server must be exist on the SVM.
- The local users and groups SMB server option must be enabled.
- The local or domain user or group to which the SeChangeNotifyPrivilege privilege will be added must already exist.

#### About this task

When adding privileges to a domain user or group, ONTAP might validate the domain user or group by contacting the domain controller. The command might fail if ONTAP cannot contact the domain controller.

#### Steps

1. Enable bypass traverse checking by adding the SeChangeNotifyPrivilege privilege to a local or domain user or group: `vserver cifs users-and-groups privilege add-privilege -vserver vserver_name -user-or-group-name name -privileges SeChangeNotifyPrivilege`

The value for the `-user-or-group-name` parameter is a local user or group, or a domain user or group.

2. Verify that the specified user or group has bypass traverse checking enabled: `vserver cifs users-and-groups privilege show -vserver vserver_name -user-or-group-name name`

#### Example

The following command enables users that belong to the “EXAMPLE\eng” group to bypass directory traverse checking by adding the SeChangeNotifyPrivilege privilege to the group:

```
cluster1::> vserver cifs users-and-groups privilege add-privilege -vserver vs1 -user-or-group-name EXAMPLE\eng -privileges SeChangeNotifyPrivilege

cluster1::> vserver cifs users-and-groups privilege show -vserver vs1
Vserver User or Group Name Privileges

vs1 EXAMPLE\eng SeChangeNotifyPrivilege
```

#### Related information

##### [Disallowing users or groups from bypassing directory traverse checking](#)

##### [Disallow users or groups from bypassing directory traverse checking](#)

If you do not want a user to traverse all the directories in the path to a file because the user does not have permissions on the traversed directory, you can remove the

SeChangeNotifyPrivilege privilege from local SMB users or groups on storage virtual machines (SVMs).

### Before you begin

The local or domain user or group from which privileges will be removed must already exist.

### About this task

When removing privileges from a domain user or group, ONTAP might validate the domain user or group by contacting the domain controller. The command might fail if ONTAP cannot contact the domain controller.

### Steps

1. Disallow bypass traverse checking: vserver cifs users-and-groups privilege remove-privilege -vserver vserver\_name -user-or-group-name name -privileges SeChangeNotifyPrivilege

The command removes the SeChangeNotifyPrivilege privilege from the local or domain user or group that you specify with the value for the -user-or-group-name *name* parameter.

2. Verify that the specified user or group has bypass traverse checking disabled: vserver cifs users-and-groups privilege show -vserver vserver\_name -user-or-group-name name

### Example

The following command disallows users that belong to the “EXAMPLE\eng” group from bypassing directory traverse checking:

```
cluster1::> vserver cifs users-and-groups privilege show -vserver vs1
Vserver User or Group Name Privileges

vs1 EXAMPLE\eng SeChangeNotifyPrivilege

cluster1::> vserver cifs users-and-groups privilege remove-privilege
-vserver vs1 -user-or-group-name EXAMPLE\eng -privileges
SeChangeNotifyPrivilege

cluster1::> vserver cifs users-and-groups privilege show -vserver vs1
Vserver User or Group Name Privileges

vs1 EXAMPLE\eng -
```

### Related information

[Allowing users or groups to bypass directory traverse checking](#)

### Display information about file security and audit policies

[Display information about file security and audit policies overview](#)

You can display information about file security on files and directories contained within volumes on storage virtual machines (SVMs). You can display information about audit

policies on FlexVol volumes. If configured, you can display information about Storage-Level Access Guard and Dynamic Access Control security settings on FlexVol volumes.

### Displaying information about file security

You can display information about file security applied to data contained within volumes and qtrees (for FlexVol volumes) with the following security styles:

- NTFS
- UNIX
- Mixed

### Displaying information about audit policies

You can display information about audit policies for auditing access events on FlexVol volumes over the following NAS protocols:

- SMB (all versions)
- NFSv4.x

### Displaying information about Storage-Level Access Guard (SLAG) security

Storage-Level Access Guard security can be applied on FlexVol volumes and qtree objects with the following security styles:

- NTFS
- Mixed
- UNIX (if a CIFS server is configured on the SVM that contains the volume)

### Displaying information about Dynamic Access Control (DAC) security

Dynamic Access Control security can be applied on an object within a FlexVol volume with the following security styles:

- NTFS
- Mixed (if the object has NTFS effective security)

#### Related information

[Securing file access by using Storage-Level Access Guard](#)

[Displaying information about Storage-Level Access Guard](#)

#### [Display information about file security on NTFS security-style volumes](#)

You can display information about file and directory security on NTFS security-style volumes, including what the security style and effective security styles are, what permissions are applied, and information about DOS attributes. You can use the results to validate your security configuration or to troubleshoot file access issues.

#### About this task

You must supply the name of the storage virtual machine (SVM) and the path to the data whose file or folder security information you want to display. You can display the output in summary form or as a detailed list.

- Because NTFS security-style volumes and qtrees use only NTFS file permissions and Windows users and groups when determining file access rights, UNIX-related output fields contain display-only UNIX file permission information.
- ACL output is displayed for file and folders with NTFS security.
- Because Storage-Level Access Guard security can be configured on the volume root or qtree, output for a volume or qtree path where Storage-Level Access Guard is configured might display both regular file ACLs and Storage-Level Access Guard ACLs.
- The output also displays information about Dynamic Access Control ACEs if Dynamic Access Control is configured for the given file or directory path.

### Step

1. Display file and directory security settings with the desired level of detail:

| If you want to display information... | Enter the following command...                                                                                             |
|---------------------------------------|----------------------------------------------------------------------------------------------------------------------------|
| In summary form                       | <code>vserver security file-directory show<br/>-vserver <i>vserver_name</i> -path <i>path</i></code>                       |
| With expanded detail                  | <code>vserver security file-directory show<br/>-vserver <i>vserver_name</i> -path <i>path</i><br/>-expand-mask true</code> |

### Examples

The following example displays the security information about the path /vol14 in SVM vs1:

```

cluster::> vserver security file-directory show -vserver vs1 -path /vol4

 Vserver: vs1
 File Path: /vol4
 File Inode Number: 64
 Security Style: ntfs
 Effective Style: ntfs
 DOS Attributes: 10
 DOS Attributes in Text: ----D---

## Related information

[Displaying information about file security on mixed security-style volumes](#)

[Displaying information about file security on UNIX security-style volumes](#)

## Display information about file security on mixed security-style volumes

You can display information about file and directory security on mixed security-style volumes, including what the security style and effective security styles are, what permissions are applied, and information about UNIX owners and groups. You can use the results to validate your security configuration or to troubleshoot file access issues.

### About this task

You must supply the name of the storage virtual machine (SVM) and the path to the data whose file or folder security information you want to display. You can display the output in summary form or as a detailed list.

- Mixed security-style volumes and qtrees can contain some files and folders that use UNIX file permissions, either mode bits or NFSv4 ACLs, and some files and directories that use NTFS file permissions.
- The top level of a mixed security-style volume can have either UNIX or NTFS effective security.
- ACL output is displayed only for file and folders with NTFS or NFSv4 security.

This field is empty for files and directories using UNIX security that have only mode bit permissions applied (no NFSv4 ACLs).

- The owner and group output fields in the ACL output apply only in the case of NTFS security descriptors.
- Because Storage-Level Access Guard security can be configured on a mixed security-style volume or qtree even if the effective security style of the volume root or qtree is UNIX, output for a volume or qtree path where Storage-Level Access Guard is configured might display both UNIX file permissions and Storage-Level Access Guard ACLs.
- If the path entered in the command is to data with NTFS effective security, the output also displays information about Dynamic Access Control ACEs if Dynamic Access Control is configured for the given file or directory path.

### Step

1. Display file and directory security settings with the desired level of detail:

| If you want to display information... | Enter the following command...                                                                             |
|---------------------------------------|------------------------------------------------------------------------------------------------------------|
| In summary form                       | <pre>vserver security file-directory show<br/>-vserver vserver_name -path path</pre>                       |
| With expanded detail                  | <pre>vserver security file-directory show<br/>-vserver vserver_name -path path<br/>-expand-mask true</pre> |

### Examples

The following example displays the security information about the path /projects in SVM vs1 in expanded-mask form. This mixed security-style path has UNIX effective security.

```
cluster1::> vserver security file-directory show -vserver vs1 -path
/projects -expand-mask true

 Vserver: vs1
 File Path: /projects
 File Inode Number: 78
 Security Style: mixed
 Effective Style: unix
 DOS Attributes: 10
 DOS Attributes in Text: ----D---
Expanded Dos Attributes: 0x10
....0 = Offline
.... .0. = Sparse
.... 0... = Normal
....0. = Archive
....1 = Directory
....0.. = System
....0. = Hidden
....0 = Read Only
 Unix User Id: 0
 Unix Group Id: 1
 Unix Mode Bits: 700
Unix Mode Bits in Text: rwx-----
 ACLs: -
```

The following example displays the security information about the path /data in SVM vs1. This mixed security-style path has an NTFS effective security.

```
cluster1::> vserver security file-directory show -vserver vs1 -path /data

 Vserver: vs1
 File Path: /data
 File Inode Number: 544
 Security Style: mixed
 Effective Style: ntfs
 DOS Attributes: 10
 DOS Attributes in Text: ----D---
 Expanded Dos Attributes: -
 Unix User Id: 0
 Unix Group Id: 0
 Unix Mode Bits: 777
 Unix Mode Bits in Text: rwxrwxrwx
 ACLs: NTFS Security Descriptor
 Control:0x8004
 Owner:BUILTIN\Administrators
 Group:BUILTIN\Administrators
 DACL - ACES
 ALLOW-Everyone-0x1f01ff
 ALLOW-Everyone-0x10000000-
OI|CI|IO
```

The following example displays the security information about the volume at the path /datavol5 in SVM vs1. The top level of this mixed security-style volume has UNIX effective security. The volume has Storage-Level Access Guard security.

```
cluster1::> vserver security file-directory show -vserver vs1 -path /datavol5
 Vserver: vs1
 File Path: /datavol5
 File Inode Number: 3374
 Security Style: mixed
 Effective Style: unix
 DOS Attributes: 10
 DOS Attributes in Text: ----D---
 Expanded Dos Attributes: -
 Unix User Id: 0
 Unix Group Id: 0
 Unix Mode Bits: 755
 Unix Mode Bits in Text: rwxr-xr-x
 ACLs: Storage-Level Access Guard security

[Displaying information about file security on UNIX security-style volumes](#)

[Display information about file security on UNIX security-style volumes](#)

You can display information about file and directory security on UNIX security-style volumes, including what the security styles and effective security styles are, what permissions are applied, and information about UNIX owners and groups. You can use

the results to validate your security configuration or to troubleshoot file access issues.

### About this task

You must supply the name of the storage virtual machine (SVM) and the path to the data whose file or directory security information you want to display. You can display the output in summary form or as a detailed list.

- UNIX security-style volumes and qtrees use only UNIX file permissions, either mode bits or NFSv4 ACLs when determining file access rights.
- ACL output is displayed only for file and folders with NFSv4 security.

This field is empty for files and directories using UNIX security that have only mode bit permissions applied (no NFSv4 ACLs).

- The owner and group output fields in the ACL output does not apply in the case of NFSv4 security descriptors.

They are only meaningful for NTFS security descriptors.

- Because Storage-Level Access Guard security is supported on a UNIX volume or qtree if a CIFS server is configured on the SVM, the output might contain information about Storage-Level Access Guard security applied to the volume or qtree specified in the `-path` parameter.

### Step

1. Display file and directory security settings with the desired level of detail:

| If you want to display information... | Enter the following command...                                                                       |
|---------------------------------------|------------------------------------------------------------------------------------------------------|
| In summary form                       | <code>vserver security file-directory show -vserver vserver_name -path path</code>                   |
| With expanded detail                  | <code>vserver security file-directory show -vserver vserver_name -path path -expand-mask true</code> |

### Examples

The following example displays the security information about the path `/home` in SVM `vs1`:

```
cluster1::> vserver security file-directory show -vserver vs1 -path /home

 Vserver: vs1
 File Path: /home
 File Inode Number: 9590
 Security Style: unix
 Effective Style: unix
 DOS Attributes: 10
 DOS Attributes in Text: ----D---
 Expanded Dos Attributes: -
 Unix User Id: 0
 Unix Group Id: 1
 Unix Mode Bits: 700
 Unix Mode Bits in Text: rwx-----
 ACLs: -
```

The following example displays the security information about the path /home in SVM vs1 in expanded-mask form:

```
cluster1::> vserver security file-directory show -vserver vs1 -path /home
-expand-mask true

 Vserver: vs1
 File Path: /home
 File Inode Number: 9590
 Security Style: unix
 Effective Style: unix
 DOS Attributes: 10
 DOS Attributes in Text: ----D---
 Expanded Dos Attributes: 0x10
 ...0 = Offline
 0. = Sparse
 0... = Normal
 0. = Archive
 1 = Directory
 0.. = System
 0. = Hidden
 0 = Read Only
 Unix User Id: 0
 Unix Group Id: 1
 Unix Mode Bits: 700
 Unix Mode Bits in Text: rwx-----
 ACLs: -
```

## Related information

[Displaying information about file security on NTFS security-style volumes](#)

[Displaying information about file security on mixed security-style volumes](#)

[Display information about NTFS audit policies on FlexVol volumes using the CLI](#)

You can display information about NTFS audit policies on FlexVol volumes, including what the security styles and effective security styles are, what permissions are applied, and information about system access control lists. You can use the results to validate your security configuration or to troubleshoot auditing issues.

## About this task

You must provide the name of the storage virtual machine (SVM) and the path to the files or folders whose audit information you want to display. You can display the output in summary form or as a detailed list.

- NTFS security-style volumes and qtrees use only NTFS system access control lists (SACLs) for audit policies.
- Files and folders in a mixed security-style volume with NTFS effective security can have NTFS audit policies applied to them.

Mixed security-style volumes and qtrees can contain some files and directories that use UNIX file permissions, either mode bits or NFSv4 ACLs, and some files and directories that use NTFS file permissions.

- The top level of a mixed security-style volume can have either UNIX or NTFS effective security and might or might not contain NTFS SACLs.
- Because Storage-Level Access Guard security can be configured on a mixed security-style volume or qtree even if the effective security style of the volume root or qtree is UNIX, the output for a volume or qtree path where Storage-Level Access Guard is configured might display both regular file and folder NFSv4 SACLs and Storage-Level Access Guard NTFS SACLs.
- If the path that is entered in the command is to data with NTFS effective security, the output also displays information about Dynamic Access Control ACEs if Dynamic Access Control is configured for the given file or directory path.
- When displaying security information about files and folders with NTFS effective security, UNIX-related output fields contain display-only UNIX file permission information.

NTFS security-style files and folders use only NTFS file permissions and Windows users and groups when determining file access rights.

- ACL output is displayed only for files and folders with NTFS or NFSv4 security.

This field is empty for files and folders using UNIX security that have only mode bit permissions applied (no NFSv4 ACLs).

- The owner and group output fields in the ACL output apply only in the case of NTFS security descriptors.

## Step

1. Display file and directory audit policy settings with the desired level of detail:

| If you want to display information... | Enter the following command...                                                                |
|---------------------------------------|-----------------------------------------------------------------------------------------------|
| In summary form                       | vserver security file-directory show<br>-vserver vserver_name -path path                      |
| As a detailed list                    | vserver security file-directory show<br>-vserver vserver_name -path path<br>-expand-mask true |

## Examples

The following example displays the audit policy information for the path /corp in SVM vs1. The path has NTFS effective security. The NTFS security descriptor contains both a SUCCESS and a SUCCESS/FAIL SACL entry.

```
cluster::> vserver security file-directory show -vserver vs1 -path /corp
 Vserver: vs1
 File Path: /corp
 File Inode Number: 357
 Security Style: ntfs
 Effective Style: ntfs
 DOS Attributes: 10

#### Display information about NFSv4 audit policies on FlexVol volumes using the CLI

You can display information about NFSv4 audit policies on FlexVol volumes using the ONTAP CLI, including what the security styles and effective security styles are, what

permissions are applied, and information about system access control lists (SACLs). You can use the results to validate your security configuration or to troubleshoot auditing issues.

### About this task

You must supply the name of the storage virtual machine (SVM) and the path to the files or directories whose audit information you want to display. You can display the output in summary form or as a detailed list.

- UNIX security-style volumes and qtrees use only NFSv4 SACLs for audit policies.
- Files and directories in a mixed security-style volume that are of UNIX security style can have NFSv4 audit policies applied to them.

Mixed security-style volumes and qtrees can contain some files and directories that use UNIX file permissions, either mode bits or NFSv4 ACLs, and some files and directories that use NTFS file permissions.

- The top level of a mixed security-style volume can have either UNIX or NTFS effective security and might or might not contain NFSv4 SACLs.
- ACL output is displayed only for file and folders with NTFS or NFSv4 security.

This field is empty for files and folders using UNIX security that have only mode bit permissions applied (no NFSv4 ACLs).

- The owner and group output fields in the ACL output apply only in the case of NTFS security descriptors.
- Because Storage-Level Access Guard security can be configured on a mixed security-style volume or qtree even if the effective security style of the volume root or qtree is UNIX, output for a volume or qtree path where Storage-Level Access Guard is configured might display both regular NFSv4 file and directory SACLs and Storage-Level Access Guard NTFS SACLs.
- Because Storage-Level Access Guard security is supported on a UNIX volume or qtree if a CIFS server is configured on the SVM, the output might contain information about Storage-Level Access Guard security applied to the volume or qtree specified in the `-path` parameter.

### Steps

1. Display file and directory security settings with the desired level of detail:

| If you want to display information... | Enter the following command...                                                                               |
|---------------------------------------|--------------------------------------------------------------------------------------------------------------|
| In summary form                       | <code>vserver security file-directory show<br/>-vserver vserver_name -path path</code>                       |
| With expanded detail                  | <code>vserver security file-directory show<br/>-vserver vserver_name -path path<br/>-expand-mask true</code> |

### Examples

The following example displays the security information about the path `/lab` in SVM vs1. This UNIX security-style path has an NFSv4 SACL.

```
cluster::> vserver security file-directory show -vserver vs1 -path /lab

 Vserver: vs1
 File Path: /lab
 File Inode Number: 288
 Security Style: unix
 Effective Style: unix
 DOS Attributes: 11
 DOS Attributes in Text: ----D--R
 Expanded Dos Attributes: -
 Unix User Id: 0
 Unix Group Id: 0
 Unix Mode Bits: 0
 Unix Mode Bits in Text: -----
 ACLs: NFSV4 Security Descriptor
 Control:0x8014
 SACL - ACEs
 SUCCESSFUL-S-1-520-0-0xf01ff-SA
 FAILED-S-1-520-0-0xf01ff-FA
 DACL - ACEs
 ALLOW-S-1-520-1-0xf01ff
```

#### **Ways to display information about file security and audit policies**

You can use the wildcard character (\*) to display information about file security and audit policies of all files and directories under a given path or a root volume.

The wildcard character () can be used as the last subcomponent of a given directory path below which you want to display information of all files and directories. If you want to display information of a particular file or directory named as "", then you need to provide the complete path inside double quotes ("`").

#### **Example**

The following command with the wildcard character displays the information about all files and directories below the path /1/ of SVM vs1:

```

cluster::> vserver security file-directory show -vserver vs1 -path /1/*
 Vserver: vs1
 File Path: /1/1
 Security Style: mixed
 Effective Style: ntfs
 DOS Attributes: 10
 DOS Attributes in Text: ----D---
 Expanded Dos Attributes: -
 Unix User Id: 0
 Unix Group Id: 0
 Unix Mode Bits: 777

## Manage NTFS file security, NTFS audit policies, and Storage-Level Access Guard on SVMs using the CLI

[Manage NTFS file security, NTFS audit policies, and Storage-Level Access Guard on SVMs using the CLI overview](#)

You can manage NTFS file security, NTFS audit policies, and Storage-Level Access Guard on storage virtual machines (SVMs) by using the CLI.

You can manage NTFS file security and audit policies from SMB clients or by using the CLI. However, using the CLI to configure file security and audit policies removes the need to use a remote client to manage file security. Using the CLI can significantly reduce the time it takes to apply security on many files and folders using a single command.

You can configure Storage-Level Access Guard, which is another layer of security applied by ONTAP to SVM volumes. Storage-Level Access Guard applies to accesses from all NAS protocols to the storage object to which Storage-Level Access Guard is applied.

Storage-Level Access Guard can be configured and managed only from the ONTAP CLI. You cannot manage Storage-Level Access Guard settings from SMB clients. Moreover, if you view the security settings on a file or directory from an NFS or SMB client, you will not see the Storage-Level Access Guard security. Storage-Level Access Guard security cannot be revoked from a client, even by a system (Windows or UNIX) administrator. Therefore, Storage-Level Access Guard provides an extra layer of security for data access that is independently set and managed by the storage administrator.

Even though only NTFS access permissions are supported for Storage-Level Access Guard, ONTAP can perform security checks for access over NFS to data on volumes where Storage-Level Access Guard is applied if the UNIX user maps to a Windows user on the SVM that owns the volume.

## NTFS security-style volumes

All files and folders contained within NTFS security-style volumes and qtrees have NTFS effective security. You can use the `vserver security file-directory` command family to implement the following types of security on NTFS security-style volumes:

- File permissions and audit policies to files and folders contained in the volume
- Storage-Level Access Guard security on volumes

## Mixed security-style volumes

Mixed security-style volumes and qtrees can contain some files and folders that have UNIX effective security and use UNIX file permissions, either mode bits or NFSv4.x ACLs and NFSv4.x audit policies, and some files and folders that have NTFS effective security and use NTFS file permissions and audit policies. You can use the `vserver security file-directory` command family to apply the following types of security to mixed security-style data:

- File permissions and audit policies to files and folders with NTFS effective security-style in the mixed volume or qtree
- Storage-Level Access Guard to volumes with either NTFS and UNIX effective security-style

## UNIX security-style volumes

UNIX security-style volumes and qtrees contain files and folders that have UNIX effective security (either mode bits or NFSv4.x ACLs). You must keep the following in mind if you want to use the `vserver security file-directory` command family to implement security on UNIX security-style volumes:

- The `vserver security file-directory` command family cannot be used to manage UNIX file security and audit policies on UNIX security-style volumes and qtrees.
- You can use the `vserver security file-directory` command family to configure Storage-Level Access Guard on UNIX security-style volumes, provided the SVM with the target volume contains a CIFS server.

### Related information

[Display information about file security and audit policies](#)

[Configure and apply file security on NTFS files and folders using the CLI](#)

[Configure and apply audit policies to NTFS files and folders using the CLI](#)

[Secure file access by using Storage-Level Access Guard](#)

### Use cases for using the CLI to set file and folder security

Because you can apply and manage file and folder security locally without involvement from a remote client, you can significantly reduce the time it takes to set bulk security on a large number of files or folders.

You can benefit from using the CLI to set file and folder security in the following use cases:

- Storage of files in large enterprise environments, such as file storage in home directories
- Migration of data
- Change of Windows domain
- Standardization of file security and audit policies across NTFS file systems

#### Limits when using the CLI to set file and folder security

You need to be aware of certain limits when using the CLI to set file and folder security.

- The `vserver security file-directory` command family does not support setting NFSv4 ACLs.

You can only apply NTFS security descriptors to NTFS files and folders.

#### How security descriptors are used to apply file and folder security

Security descriptors contain the access control lists that determine what actions a user can perform on files and folders, and what is audited when a user accesses files and folders.

- **Permissions**

Permissions are allowed or denied by an object's owner and determine what actions an object (users, groups, or computer objects) can perform on specified files or folders.

- **Security descriptors**

Security descriptors are data structures that contain security information that define permissions associated with a file or folder.

- **Access control lists (ACLs)**

Access control lists are the lists contained within a security descriptor that contain information on what actions users, groups, or computer objects can perform on the file or folder to which the security descriptor is applied. The security descriptor can contain the following two types of ACLs:

- Discretionary access control lists (DACLs)
- System access control lists (SACLs)

- **Discretionary access control lists (DACLs)**

DACLs contain the list of SIDS for the users, groups, and computer objects who are allowed or denied access to perform actions on files or folders. DACLs contain zero or more access control entries (ACEs).

- **System access control lists (SACLs)**

SACLs contain the list of SIDS for the users, groups, and computer objects for which successful or failed auditing events are logged. SACLs contain zero or more access control entries (ACEs).

- **Access Control Entries (ACEs)**

ACEs are individual entries in either DACLs or SACLs:

- A DACL access control entry specifies the access rights that are allowed or denied for particular users, groups, or computer objects.
- A SACL access control entry specifies the success or failure events to log when auditing specified actions performed by particular users, groups, or computer objects.

- **Permission inheritance**

Permission inheritance describes how permissions defined in security descriptors are propagated to an object from a parent object. Only inheritable permissions are inherited by child objects. When setting permissions on the parent object, you can decide whether folders, sub-folders, and files can inherit them with “Apply to this-folder, sub-folders, and files”.

## Guidelines for applying file-directory policies that use local users or groups on the SVM disaster recovery destination

There are certain guidelines that you must keep in mind before applying file-directory policies on the storage virtual machine (SVM) disaster recovery destination in an ID discard configuration if your file-directory policy configuration uses local users or groups in either the security descriptor or the DACL or SACL entries.

You can configure a disaster recovery configuration for an SVM where the source SVM on the source cluster replicates the data and configuration from the source SVM to a destination SVM on a destination cluster.

You can set up one of two types of SVM disaster recovery:

- Identity preserved

With this configuration, the identity of the SVM and the CIFS server is preserved.

- Identity discarded

With this configuration, the identity of the SVM and the CIFS server is not preserved. In this scenario, the name of the SVM and the CIFS server on the destination SVM is different from the SVM and the CIFS server name on the source SVM.

## Guidelines for identity discarded configurations

In an identity discarded configuration, for an SVM source that contains local user, group, and privilege configurations, the name of the local domain (local CIFS server name) must be changed to match the CIFS server name on the SVM destination. For example, if the source SVM name is “vs1” and CIFS server name is “CIFS1”, and the destination SVM name is “vs1\_dst” and the CIFS server name is “CIFS1\_DST”, then the local domain name for a local user named “CIFS1\user1” is automatically changed to “CIFS1\_DST\user1” on the destination SVM:

```
cluster1::> vserver cifs users-and-groups local-user show -vserver vs1_dst
```

| Vserver | User Name           | Full Name | Description                       |
|---------|---------------------|-----------|-----------------------------------|
| vs1     | CIFS1\Administrator |           | Built-in<br>administrator account |
| vs1     | CIFS1\user1         | -         | -                                 |

```
cluster1dst::> vserver cifs users-and-groups local-user show -vserver
vs1_dst
```

| Vserver | User Name               | Full Name | Description                       |
|---------|-------------------------|-----------|-----------------------------------|
| vs1_dst | CIFS1_DST\Administrator |           | Built-in<br>administrator account |
| vs1_dst | CIFS1_DST\user1         | -         | -                                 |

Even though local user and group names are automatically changed in the local user and group databases, local users or group names are not automatically changed in file-directory policy configurations (policies configured on the CLI using the `vserver security file-directory` command family).

For example, for “vs1”, if you have configured a DACL entry where the `-account` parameter is set to “CIFS1\user1”, the setting is not automatically changed on the destination SVM to reflect the destination’s CIFS server name.

```
cluster1::> vserver security file-directory ntfs dacl show -vserver vs1
```

Vserver: vs1

NTFS Security Descriptor Name: sd1

| Account Name | Access Type | Access Rights | Apply To    |
|--------------|-------------|---------------|-------------|
| CIFS1\user1  | allow       | full-control  | this-folder |

```
cluster1::> vserver security file-directory ntfs dacl show -vserver
vs1_dst
```

Vserver: vs1\_dst

NTFS Security Descriptor Name: sd1

| Account Name    | Access Type | Access Rights | Apply To    |
|-----------------|-------------|---------------|-------------|
| **CIFS1**\user1 | allow       | full-control  | this-folder |

You must use the `vserver security file-directory modify` commands to manually change the CIFS server name to the destination CIFS server name.

## File-directory policy configuration components that contain account parameters

There are three file-directory policy configuration components that can use parameter settings that can contain local users or groups:

- Security descriptor

You can optionally specify the owner of the security descriptor and the primary group of the owner of the security descriptor. If the security descriptor uses a local user or group for the owner and primary group entries, you must modify the security descriptor to use the destination SVM in the account name. You can use the `vserver security file-directory ntfs modify` command to make any necessary changes to the account names.

- DACL entries

Each DACL entry must be associated with an account. You must modify any DACLs that use local user or group accounts to use the destination SVM name. Because you cannot modify the account name for existing DACL entries, you must remove any DACL entries with local users or groups from the security descriptors, create new DACL entries with the corrected destination account names, and associate these new DACL entries with the appropriate security descriptors.

- SACL entries

Each SACL entry must be associated with an account. You must modify any SACLs that use local user or group accounts to use the destination SVM name. Because you cannot modify the account name for existing SACL entries, you must remove any SACL entries with local users or groups from the security descriptors, create new SACL entries with the corrected destination account names, and associate these new SACL entries with the appropriate security descriptors.

You must make any necessary changes to local users or groups used in the file-directory policy configuration before applying the policy; otherwise, the apply job fails.

## Configure and apply file security on NTFS files and folders using the CLI

### Create an NTFS security descriptor

Creating an NTFS security descriptor (file security policy) is the first step in configuring and applying NTFS access control lists (ACLs) to files and folders residing within storage virtual machines (SVMs). You can associate the security descriptor to the file or folder path in a policy task.

### About this task

You can create NTFS security descriptors for files and folders residing within NTFS security-style volumes, or for files and folders residing on mixed security-style volumes.

By default, when a security descriptor is created, four discretionary access control list (DACL) access control entries (ACEs) are added to that security descriptor. The four default ACEs are as follows:

| Object                 | Access type | Access rights | Where to apply the permissions  |
|------------------------|-------------|---------------|---------------------------------|
| BUILTIN\Administrators | Allow       | Full Control  | this-folder, sub-folders, files |
| BUILTIN\Users          | Allow       | Full Control  | this-folder, sub-folders, files |
| CREATOR OWNER          | Allow       | Full Control  | this-folder, sub-folders, files |
| NT AUTHORITY\SYSTEM    | Allow       | Full Control  | this-folder, sub-folders, files |

You can customize the security descriptor configuration by using the following optional parameters:

- Owner of the security descriptor
- Primary group of the owner
- Raw control flags

The value for any optional parameter is ignored for Storage-Level Access Guard. See the man pages for more information.

### Add NTFS DACL access control entries to the NTFS security descriptor

Adding DACL (discretionary access control list) access control entries (ACEs) to the NTFS security descriptor is the second step in configuring and applying NTFS ACLs to a file or folder. Each entry identifies which object is allowed or denied access, and defines what the object can or cannot do to the files or folders defined in the ACE.

#### About this task

You can add one or more ACEs to the security descriptor's DACL.

If the security descriptor contains a DACL that has existing ACEs, the command adds the new ACE to the DACL. If the security descriptor does not contain a DACL, the command creates the DACL and adds the new ACE to it.

You can optionally customize DACL entries by specifying what rights you want to allow or deny for the account specified in the –account parameter. There are three mutually exclusive methods for specifying rights:

- Rights
- Advanced rights
- Raw rights (advanced-privilege)

If you do not specify rights for the DACL entry, the default is to set the rights to Full Control.

You can optionally customize DACL entries by specifying how to apply inheritance.

The value for any optional parameter is ignored for Storage-Level Access Guard. See the man pages for more information.

## Steps

1. Add a DACL entry to a security descriptor: `vserver security file-directory ntfs dacl add -vserver vserver_name -ntfs-sd SD_name -access-type {allow|deny} -account name_or_SID optional_parameters`

```
vserver security file-directory ntfs dacl add -ntfs-sd sd1 -access-type deny -account domain\joe -rights full-control -apply-to this-folder -vserver vs1
```

2. Verify that the DACL entry is correct: `vserver security file-directory ntfs dacl show -vserver vserver_name -ntfs-sd SD_name -access-type {allow|deny} -account name_or_SID`

```
vserver security file-directory ntfs dacl show -vserver vs1 -ntfs-sd sd1 -access-type deny -account domain\joe
```

```
Vserver: vs1
Security Descriptor Name: sd1
Allow or Deny: deny
Account Name or SID: DOMAIN\joe
Access Rights: full-control
Advanced Access Rights: -
Apply To: this-folder
Access Rights: full-control
```

## Create security policies

Creating a file security policy for SVMs is the third step in configuring and applying ACLs to a file or folder. A policy acts as a container for various tasks, where each task is a single entry that can be applied to files or folders. You can add tasks to the security policy later.

### About this task

The tasks that you add to a security policy contain associations between the NTFS security descriptor and the file or folder paths. Therefore, you should associate the security policy with each SVM (containing NTFS security-style volumes or mixed security-style volumes).

## Steps

1. Create a security policy: `vserver security file-directory policy create -vserver vserver_name -policy-name policy_name`

```
vserver security file-directory policy create -policy-name policy1 -vserver vs1
```

2. Verify the security policy: `vserver security file-directory policy show`

```
vserver security file-directory policy show
 Vserver Policy Name

 vs1 policy1
```

## Add a task to the security policy

Creating and adding a policy task to a security policy is the fourth step in configuring and applying ACLs to files or folders in SVMs. When you create the policy task, you associate the task with a security policy. You can add one or more task entries to a security policy.

### About this task

The security policy is a container for a task. A task refers to a single operation that can be done by a security policy to files or folders with NTFS or mixed security (or to a volume object if configuring Storage-Level Access Guard).

There are two types of tasks:

- File and directory tasks

Used to specify tasks that apply security descriptors to specified files and folders. ACLs applied through file and directory tasks can be managed with SMB clients or the ONTAP CLI.

- Storage-Level Access Guard tasks

Used to specify tasks that apply Storage-Level Access Guard security descriptors to a specified volume. ACLs applied through Storage-Level Access Guard tasks can be managed only through the ONTAP CLI.

A task contains definitions for the security configuration of a file (or folder) or set of files (or folders). Every task in a policy is uniquely identified by the path. There can be only one task per path within a single policy. A policy cannot have duplicate task entries.

Guidelines for adding a task to a policy:

- There can be a maximum of 10,000 tasks entries per policy.
- A policy can contain one or more tasks.

Even though a policy can contain more than one task, you cannot configure a policy to contain both file-directory and Storage-Level Access Guard tasks. A policy must contain either all Storage-Level Access Guard tasks or all file-directory tasks.

- Storage-Level Access Guard is used to restrict permissions.

It will never give extra access permissions.

When adding tasks to security policies, you must specify the following four required parameters:

- SVM name
- Policy name

- Path
- Security descriptor to associate with the path

You can customize the security descriptor configuration by using the following optional parameters:

- Security type
- Propagation mode
- Index position
- Access control type

The value for any optional parameter is ignored for Storage-Level Access Guard. See the man pages for more information.

## Steps

1. Add a task with an associated security descriptor to the security policy: `vserver security file-directory policy task add -vserver vserver_name -policy-name policy_name -path path -ntfs-sd SD_nameoptional_parameters`

`file-directory` is the default value for the `-access-control` parameter. Specifying the access control type when configuring file and directory access tasks is optional.

```
vserver security file-directory policy task add -vserver vs1 -policy-name
policy1 -path /home/dirl1 -security-type ntfs -ntfs-mode propagate -ntfs-sd sd2
-index-num 1 -access-control file-directory
```

2. Verify the policy task configuration: `vserver security file-directory policy task show -vserver vserver_name -policy-name policy_name -path path`

```
vserver security file-directory policy task show
```

|              |                 |       |                |        |           |       |       |
|--------------|-----------------|-------|----------------|--------|-----------|-------|-------|
| Vserver: vs1 | Policy: policy1 | Index | File/Folder    | Access | Security  | NTFS  | NTFS  |
| Security     |                 |       |                |        | Type      | Mode  |       |
| Descriptor   | Path            |       | Control        |        |           |       |       |
| Name         |                 |       |                |        |           |       |       |
| -----        | -----           | ----- | -----          | -----  | -----     | ----- | ----- |
| -----        | -----           | ----- | -----          | -----  | -----     | ----- | ----- |
| 1            | /home/dirl1     |       | file-directory | ntfs   | propagate | sd2   |       |

## Apply security policies

Applying a file security policy to SVMs is the last step in creating and applying NTFS ACLs to files or folders.

## About this task

You can apply security settings defined in the security policy to NTFS files and folders residing within FlexVol volumes (NTFS or mixed security style).

- When an audit policy and associated SACLs are applied, any existing DACLs are overwritten.  
When a security policy and its associated DACLs are applied, any existing DACLs are overwritten. You should review existing security policies before creating and applying new ones.

## Step

1. Apply a security policy: `vserver security file-directory apply -vserver vserver_name -policy-name policy_name`

```
vserver security file-directory apply -vserver vs1 -policy-name policy1
```

The policy apply job is scheduled and the Job ID is returned.

```
[Job 53322] Job is queued: Fsecurity Apply. Use the "Job show 53322 -id 53322" command to view the status of the operation
```

## Monitor the security policy job

When applying the security policy to storage virtual machines (SVMs), you can monitor the progress of the task by monitoring the security policy job. This is helpful if you want to ascertain that the application of the security policy succeeded. This is also helpful if you have a long-running job where you are applying bulk security to a large number of files and folders.

### About this task

To display detailed information about a security policy job, you should use the `-instance` parameter.

## Step

1. Monitor the security policy job: `vserver security file-directory job show -vserver vserver_name`

```
vserver security file-directory job show -vserver vs1
```

| Job ID | Name            | Vserver | Node  | State   |
|--------|-----------------|---------|-------|---------|
| 53322  | Fsecurity Apply | vs1     | node1 | Success |

Description: File Directory Security Apply Job

## Verify the applied file security

You can verify the file security settings to confirm that the files or folders on the storage virtual machine (SVM) to which you applied the security policy have the desired settings.

### About this task

You must supply the name of the SVM that contains the data and the path to the file and folders on which you want to verify security settings. You can use the optional `-expand-mask` parameter to display detailed information about the security settings.

## Step

1. Display file and folder security settings: `vserver security file-directory show -vserver vserver_name -path path [-expand-mask true]`

```
vserver security file-directory show -vserver vs1 -path /data/engineering
-expand-mask true
```

```

## Configure and apply audit policies to NTFS files and folders using the CLI overview

There are several steps you must perform to apply audit policies to NTFS files and folders when using the ONTAP CLI. First, you create an NTFS security descriptor and add SACLs to the security descriptor. Next you create a security policy and add policy tasks. You then apply the security policy to a storage virtual machine (SVM).

## About this task

After applying the security policy, you can monitor the security policy job and then verify the settings for the applied audit policy.

When an audit policy and associated SACLs are applied, any existing DACLs are overwritten.  
You should review existing security policies before creating and applying new ones.

[Configure and apply file security on NTFS files and folders using the CLI](#)

## Create an NTFS security descriptor

Creating an NTFS security descriptor audit policy is the first step in configuring and applying NTFS access control lists (ACLs) to files and folders residing within SVMs. You will associate the security descriptor to the file or folder path in a policy task.

## About this task

You can create NTFS security descriptors for files and folders residing within NTFS security-style volumes, or for files and folders residing on mixed security-style volumes.

By default, when a security descriptor is created, four discretionary access control list (DACL) access control entries (ACEs) are added to that security descriptor. The four default ACEs are as follows:

| Object                 | Access type | Access rights | Where to apply the permissions  |
|------------------------|-------------|---------------|---------------------------------|
| BUILTIN\Administrators | Allow       | Full Control  | this-folder, sub-folders, files |
| BUILTIN\Users          | Allow       | Full Control  | this-folder, sub-folders, files |
| CREATOR OWNER          | Allow       | Full Control  | this-folder, sub-folders, files |
| NT AUTHORITY\SYSTEM    | Allow       | Full Control  | this-folder, sub-folders, files |

You can customize the security descriptor configuration by using the following optional parameters:

- Owner of the security descriptor
- Primary group of the owner

- Raw control flags

The value for any optional parameter is ignored for Storage-Level Access Guard. See the man pages for more information.

## Steps

1. If you want to use the advanced parameters, set the privilege level to advanced: `set -privilege advanced`
2. Create a security descriptor: `vserver security file-directory ntfs create -vserver vserver_name -ntfs-sd SD_name optional_parameters`  
`vserver security file-directory ntfs create -ntfs-sd sd1 -vserver vs1 -owner DOMAIN\joe`
3. Verify that the security descriptor configuration is correct: `vserver security file-directory ntfs show -vserver vserver_name -ntfs-sd SD_name`

```
vserver security file-directory ntfs show -vserver vs1 -ntfs-sd sd1
```

```
Vserver: vs1
Security Descriptor Name: sd1
Owner of the Security Descriptor: DOMAIN\joe
```

4. If you are in the advanced privilege level, return to the admin privilege level: `set -privilege admin`

## Add NTFS SACL access control entries to the NTFS security descriptor

Adding SACL (system access control list) access control entries (ACEs) to the NTFS security descriptor is the second step in creating NTFS audit policies for files or folders in SVMs. Each entry identifies the user or group that you want to audit. The SACL entry defines whether you want to audit successful or failed access attempts.

### About this task

You can add one or more ACEs to the security descriptor's SACL.

If the security descriptor contains a SACL that has existing ACEs, the command adds the new ACE to the SACL. If the security descriptor does not contain a SACL, the command creates the SACL and adds the new ACE to it.

You can configure SACL entries by specifying what rights you want to audit for success or failure events for the account specified in the `-account` parameter. There are three mutually exclusive methods for specifying rights:

- Rights
- Advanced rights
- Raw rights (advanced-privilege)

If you do not specify rights for the SACL entry, the default setting is Full Control.

You can optionally customize SACL entries by specifying how to apply inheritance with the `apply-to` parameter. If you do not specify this parameter, the default is to apply this SACL entry to this folder, subfolders, and files.

## Steps

1. Add a SACL entry to a security descriptor: `vserver security file-directory ntfs acl add -vserver vserver_name -ntfs-sd SD_name -access-type {failure|success} -account name_or_SID optional_parameters`

```
vserver security file-directory ntfs acl add -ntfs-sd sd1 -access-type failure -account domain\joe -rights full-control -apply-to this-folder -vserver vs1
```

2. Verify that the SACL entry is correct: `vserver security file-directory ntfs acl show -vserver vserver_name -ntfs-sd SD_name -access-type {failure|success} -account name_or_SID`

```
vserver security file-directory ntfs acl show -vserver vs1 -ntfs-sd sd1 -access-type deny -account domain\joe
```

```
Vserver: vs1
Security Descriptor Name: sd1
Access type for Specified Access Rights: failure
Account Name or SID: DOMAIN\joe
Access Rights: full-control
Advanced Access Rights: -
Apply To: this-folder
Access Rights: full-control
```

## Create security policies

Creating an audit policy for storage virtual machines (SVMs) is the third step in configuring and applying ACLs to a file or folder. A policy acts as a container for various tasks, where each task is a single entry that can be applied to files or folders. You can add tasks to the security policy later.

### About this task

The tasks that you add to a security policy contain associations between the NTFS security descriptor and the file or folder paths. Therefore, you should associate the security policy with each storage virtual machine (SVM) (containing NTFS security-style volumes or mixed security-style volumes).

## Steps

1. Create a security policy: `vserver security file-directory policy create -vserver vserver_name -policy-name policy_name`

```
vserver security file-directory policy create -policy-name policy1 -vserver
```

vs1

2. Verify the security policy: vserver security file-directory policy show

```
vserver security file-directory policy show
 Vserver Policy Name

 vs1 policy1
```

## Add a task to the security policy

Creating and adding a policy task to a security policy is the fourth step in configuring and applying ACLs to files or folders in SVMs. When you create the policy task, you associate the task with a security policy. You can add one or more task entries to a security policy.

### About this task

The security policy is a container for a task. A task refers to a single operation that can be done by a security policy to files or folders with NTFS or mixed security (or to a volume object if configuring Storage-Level Access Guard).

There are two types of tasks:

- File and directory tasks

Used to specify tasks that apply security descriptors to specified files and folders. ACLs applied through file and directory tasks can be managed with SMB clients or the ONTAP CLI.

- Storage-Level Access Guard tasks

Used to specify tasks that apply Storage-Level Access Guard security descriptors to a specified volume. ACLs applied through Storage-Level Access Guard tasks can be managed only through the ONTAP CLI.

A task contains definitions for the security configuration of a file (or folder) or set of files (or folders). Every task in a policy is uniquely identified by the path. There can be only one task per path within a single policy. A policy cannot have duplicate task entries.

Guidelines for adding a task to a policy:

- There can be a maximum of 10,000 tasks entries per policy.
- A policy can contain one or more tasks.

Even though a policy can contain more than one task, you cannot configure a policy to contain both file-directory and Storage-Level Access Guard tasks. A policy must contain either all Storage-Level Access Guard tasks or all file-directory tasks.

- Storage-Level Access Guard is used to restrict permissions.

It will never give extra access permissions.

You can customize the security descriptor configuration by using the following optional parameters:

- Security type
- Propagation mode
- Index position
- Access control type

The value for any optional parameter is ignored for Storage-Level Access Guard. See the man pages for more information.

## Steps

1. Add a task with an associated security descriptor to the security policy: `vserver security file-directory policy task add -vserver vserver_name -policy-name policy_name -path path -ntfs-sd SD_nameoptional_parameters`

`file-directory` is the default value for the `-access-control` parameter. Specifying the access control type when configuring file and directory access tasks is optional.

```
vserver security file-directory policy task add -vserver vs1 -policy-name
policy1 -path /home/dir1 -security-type ntfs -ntfs-mode propagate -ntfs-sd sd2
-index-num 1 -access-control file-directory
```

2. Verify the policy task configuration: `vserver security file-directory policy task show -vserver vserver_name -policy-name policy_name -path path`

```
vserver security file-directory policy task show
```

| Vserver: vs1 |             | Policy: policy1 |          |           |       |
|--------------|-------------|-----------------|----------|-----------|-------|
| Index        | File/Folder | Access          | Security | NTFS      | NTFS  |
| Security     | Path        | Control         | Type     | Mode      |       |
| Descriptor   | Name        |                 |          |           |       |
| -----        | -----       | -----           | -----    | -----     | ----- |
| -----        | -----       | -----           | -----    | -----     | ----- |
| 1            | /home/dir1  | file-directory  | ntfs     | propagate | sd2   |

## Apply security policies

Applying an audit policy to SVMs is the last step in creating and applying NTFS ACLs to files or folders.

### About this task

You can apply security settings defined in the security policy to NTFS files and folders residing within FlexVol volumes (NTFS or mixed security style).

When an audit policy and associated SACLs are applied, any existing DACLs are overwritten. When a security policy and its associated DACLs are applied, any existing DACLs are overwritten. You should review existing security policies before creating and applying new ones.

## Step

1. Apply a security policy: `vserver security file-directory apply -vserver vserver_name -policy-name policy_name`

```
vserver security file-directory apply -vserver vs1 -policy-name policy1
```

The policy apply job is scheduled and the Job ID is returned.

```
[Job 53322] Job is queued: Fsecurity Apply. Use the "Job show 53322 -id 53322" command to view the status of the operation
```

## Monitor the security policy job

When applying the security policy to storage virtual machines (SVMs), you can monitor the progress of the task by monitoring the security policy job. This is helpful if you want to ascertain that the application of the security policy succeeded. This is also helpful if you have a long-running job where you are applying bulk security to a large number of files and folders.

### About this task

To display detailed information about a security policy job, you should use the `-instance` parameter.

## Step

1. Monitor the security policy job: `vserver security file-directory job show -vserver vserver_name`

```
vserver security file-directory job show -vserver vs1
```

| Job ID                                         | Name            | Vserver | Node  | State   |
|------------------------------------------------|-----------------|---------|-------|---------|
| 53322                                          | Fsecurity Apply | vs1     | node1 | Success |
| Description: File Directory Security Apply Job |                 |         |       |         |

## Verify the applied audit policy

You can verify the audit policy to confirm that the files or folders on the storage virtual machine (SVM) to which you applied the security policy have the desired audit security settings.

### About this task

You use the `vserver security file-directory show` command to display audit policy information. You

must supply the name of the SVM that contains the data and the path to the data whose file or folder audit policy information you want to display.

## Step

1. Display audit policy settings: `vserver security file-directory show -vserver vserver_name -path path`

## Example

The following command displays the audit policy information applied to the path “/corp” in SVM vs1. The path has both a SUCCESS and a SUCCESS/FAIL SACL entry applied to it:

```
cluster::> vserver security file-directory show -vserver vs1 -path /corp

 Vserver: vs1
 File Path: /corp
 Security Style: ntfs
 Effective Style: ntfs

```

## Considerations when managing security policy jobs

If a security policy job exists, under certain circumstances, you cannot modify that security policy or the tasks assigned to that policy. You should understand under what conditions you can or cannot modify security policies so that any attempts that you make to modify the policy are successful. Modifications to the policy include adding, removing, or modifying tasks assigned to the policy and deleting or modifying the policy.

You cannot modify a security policy or a task assigned to that policy if a job exists for that policy and that job is in the following states:

- The job is running or in progress.
- The job is paused.
- The job is resumed and is in the running state.
- If the job is waiting to failover to another node.

Under the following circumstances, if a job exists for a security policy, you can successfully modify that security policy or a task assigned to that policy:

- The policy job is stopped.
- The policy job has successfully finished.

#### **Commands for managing NTFS security descriptors**

There are specific ONTAP commands for managing security descriptors. You can create, modify, delete, and display information about security descriptors.

| If you want to...                                            | Use this command...                         |
|--------------------------------------------------------------|---------------------------------------------|
| Create NTFS security descriptors                             | vserver security file-directory ntfs create |
| Modify existing NTFS security descriptors                    | vserver security file-directory ntfs modify |
| Display information about existing NTFS security descriptors | vserver security file-directory ntfs show   |
| Delete NTFS security descriptors                             | vserver security file-directory ntfs delete |

See the man pages for the `vserver security file-directory ntfs` commands for more information.

#### **Commands for managing NTFS DACL access control entries**

There are specific ONTAP commands for managing DACL access control entries (ACEs). You can add ACEs to NTFS DACLs at any time. You can also manage existing NTFS DACLs by modifying, deleting, and displaying information about ACEs in DACLs.

| If you want to...                      | Use this command...                                           |
|----------------------------------------|---------------------------------------------------------------|
| Create ACEs and add them to NTFS DACLs | <code>vserver security file-directory ntfs dacl add</code>    |
| Modify existing ACEs in NTFS DACLs     | <code>vserver security file-directory ntfs dacl modify</code> |

| If you want to...                                     | Use this command...                              |
|-------------------------------------------------------|--------------------------------------------------|
| Display information about existing ACEs in NTFS DACLs | vserver security file-directory ntfs dacl show   |
| Remove existing ACEs from NTFS DACLs                  | vserver security file-directory ntfs dacl remove |

See the man pages for the `vserver security file-directory ntfs dacl` commands for more information.

#### Commands for managing NTFS SACL access control entries

There are specific ONTAP commands for managing SACL access control entries (ACEs). You can add ACEs to NTFS SACLs at any time. You can also manage existing NTFS SACLs by modifying, deleting, and displaying information about ACEs in SACLs.

| If you want to...                                     | Use this command...                                           |
|-------------------------------------------------------|---------------------------------------------------------------|
| Create ACEs and add them to NTFS SACLs                | <code>vserver security file-directory ntfs sacl add</code>    |
| Modify existing ACEs in NTFS SACLs                    | <code>vserver security file-directory ntfs sacl modify</code> |
| Display information about existing ACEs in NTFS SACLs | <code>vserver security file-directory ntfs sacl show</code>   |
| Remove existing ACEs from NTFS SACLs                  | <code>vserver security file-directory ntfs sacl remove</code> |

See the man pages for the `vserver security file-directory ntfs sacl` commands for more information.

#### Commands for managing security policies

There are specific ONTAP commands for managing security policies. You can display information about policies and you can delete policies. You cannot modify a security policy.

| If you want to...                           | Use this command...                                        |
|---------------------------------------------|------------------------------------------------------------|
| Create security policies                    | <code>vserver security file-directory policy create</code> |
| Display information about security policies | <code>vserver security file-directory policy show</code>   |

| If you want to...        | Use this command...                           |
|--------------------------|-----------------------------------------------|
| Delete security policies | vserver security file-directory policy delete |

See the man pages for the `vserver security file-directory policy` commands for more information.

#### Commands for managing security policy tasks

There are ONTAP commands for adding, modifying, removing, and displaying information about security policy tasks.

| If you want to...                               | Use this command...                                             |
|-------------------------------------------------|-----------------------------------------------------------------|
| Add security policy tasks                       | <code>vserver security file-directory policy task add</code>    |
| Modify security policy tasks                    | <code>vserver security file-directory policy task modify</code> |
| Display information about security policy tasks | <code>vserver security file-directory policy task show</code>   |
| Remove security policy tasks                    | <code>vserver security file-directory policy task remove</code> |

See the man pages for the `vserver security file-directory policy task` commands for more information.

#### Commands for managing security policy jobs

There are ONTAP commands for pausing, resuming, stopping, and displaying information about security policy jobs.

| If you want to...                              | Use this command...                                                                                                                   |
|------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------|
| Pause security policy jobs                     | <code>vserver security file-directory job pause -vserver vserver_name -id integer</code>                                              |
| Resume security policy jobs                    | <code>vserver security file-directory job resume -vserver vserver_name -id integer</code>                                             |
| Display information about security policy jobs | <code>vserver security file-directory job show -vserver vserver_name</code> You can determine the job ID of a job using this command. |

| If you want to...         | Use this command...                                                        |
|---------------------------|----------------------------------------------------------------------------|
| Stop security policy jobs | vserver security file-directory job stop -vserver vserver_name -id integer |

See the man pages for the `vserver security file-directory job` commands for more information.

### Configure the metadata cache for SMB shares

#### How SMB metadata caching works

Metadata caching enables file attribute caching on SMB 1.0 clients to provide faster access to file and folder attributes. You can enable or disable attribute caching on a per-share basis. You can also configure the time-to-live for cached entries if metadata caching is enabled. Configuring metadata caching is not necessary if clients are connecting to shares over SMB 2.x or SMB 3.0.

When enabled, the SMB metadata cache stores path and file attribute data for a limited amount of time. This can improve SMB performance for SMB 1.0 clients with common workloads.

For certain tasks, SMB creates a significant amount of traffic that can include multiple identical queries for path and file metadata. You can reduce the number of redundant queries and improve performance for SMB 1.0 clients by using SMB metadata caching to fetch information from the cache instead.

While unlikely, it is possible that the metadata cache might serve stale information to SMB 1.0 clients. If your environment cannot afford this risk, you should not enable this feature.

#### Enable the SMB metadata cache

You can improve SMB performance for SMB 1.0 clients by enabling the SMB metadata cache. By default, SMB metadata caching is disabled.

#### Step

1. Perform the desired action:

| If you want to...                                   | Enter the command...                                                                                                            |
|-----------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------|
| Enable SMB metadata caching when you create a share | <code>vserver cifs share create -vserver vserver_name -share-name share_name -path path -share-properties attributecache</code> |
| Enable SMB metadata caching on an existing share    | <code>vserver cifs share properties add -vserver vserver_name -share-name share_name -share-properties attributecache</code>    |

#### Related information

## [Configuring the lifetime of SMB metadata cache entries](#)

### [Adding or removing share properties on an existing SMB share](#)

#### **Configure the lifetime of SMB metadata cache entries**

You can configure the lifetime of SMB metadata cache entries to optimize the SMB metadata cache performance in your environment. The default is 10 seconds.

#### **Before you begin**

You must have enabled the SMB metadata cache feature. If SMB metadata caching is not enabled, the SMB cache TTL setting is not used.

#### **Step**

1. Perform the desired action:

| If you want to configure the lifetime of SMB metadata cache entries when you... | Enter the command...                                                                                                                                  |
|---------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------|
| Create a share                                                                  | <code>vserver cifs share -create -vserver vserver_name -share-name share_name -path path -attribute-cache-ttl [integerh] [integerm] [integers]</code> |
| Modify an existing share                                                        | <code>vserver cifs share -modify -vserver vserver_name -share-name share_name -attribute-cache-ttl [integerh] [integerm] [integers]</code>            |

You can specify additional share configuration options and properties when you create or modify shares. See the man pages for more information.

## **Manage file locks**

### **About file locking between protocols**

File locking is a method used by client applications to prevent a user from accessing a file previously opened by another user. How ONTAP locks files depends on the protocol of the client.

If the client is an NFS client, locks are advisory; if the client is an SMB client, locks are mandatory.

Because of differences between the NFS and SMB file locks, an NFS client might fail to access a file previously opened by an SMB application.

The following occurs when an NFS client attempts to access a file locked by an SMB application:

- In mixed or NTFS volumes, file manipulation operations such as `rm`, `rmdir`, and `mv` can cause the NFS application to fail.
- NFS read and write operations are denied by SMB deny-read and deny-write open modes, respectively.

- NFS write operations fail when the written range of the file is locked with an exclusive SMB bytelock.

In UNIX security-style volumes, NFS unlink and rename operations ignore SMB lock state and allow access to the file. All other NFS operations on UNIX security-style volumes honor SMB lock state.

#### How ONTAP treats read-only bits

The read-only bit is set on a file-by-file basis to reflect whether a file is writable (disabled) or read-only (enabled).

SMB clients that use Windows can set a per-file read-only bit. NFS clients do not set a per-file read-only bit because NFS clients do not have any protocol operations that use a per-file read-only bit.

ONTAP can set a read-only bit on a file when an SMB client that uses Windows creates that file. ONTAP can also set a read-only bit when a file is shared between NFS clients and SMB clients. Some software, when used by NFS clients and SMB clients, requires the read-only bit to be enabled.

For ONTAP to keep the appropriate read and write permissions on a file shared between NFS clients and SMB clients, it treats the read-only bit according to the following rules:

- NFS treats any file with the read-only bit enabled as if it has no write permission bits enabled.
- If an NFS client disables all write permission bits and at least one of those bits had previously been enabled, ONTAP enables the read-only bit for that file.
- If an NFS client enables any write permission bit, ONTAP disables the read-only bit for that file.
- If the read-only bit for a file is enabled and an NFS client attempts to discover permissions for the file, the permission bits for the file are not sent to the NFS client; instead, ONTAP sends the permission bits to the NFS client with the write permission bits masked.
- If the read-only bit for a file is enabled and an SMB client disables the read-only bit, ONTAP enables the owner's write permission bit for the file.
- Files with the read-only bit enabled are writable only by root.

Changes to file permissions take effect immediately on SMB clients, but might not take effect immediately on NFS clients if the NFS client enables attribute caching.

#### How ONTAP differs from Windows on handling locks on share path components

Unlike Windows, ONTAP does not lock each component of the path to an open file while the file is open. This behavior also affects SMB share paths.

Because ONTAP does not lock each component of the path, it is possible to rename a path component above the open file or share, which can cause problems for certain applications, or can cause the share path in the SMB configuration to be invalid. This can cause the share to be inaccessible.

To avoid issues caused by renaming path components, you can apply security settings that prevent users or applications from renaming critical directories.

#### Display information about locks

You can display information about the current file locks, including what types of locks are held and what the lock state is, details about byte-range locks, sharelock modes, delegation locks, and opportunistic locks, and whether locks are opened with durable or

persistent handles.

### About this task

The client IP address cannot be displayed for locks established through NFSv4 or NFSv4.1.

By default, the command displays information about all locks. You can use command parameters to display information about locks for a specific storage virtual machine (SVM) or to filter the command's output by other criteria.

The `vserver locks show` command displays information about four types of locks:

- Byte-range locks, which lock only a portion of a file.
- Share locks, which lock open files.
- Opportunistic locks, which control client-side caching over SMB.
- Delegations, which control client-side caching over NFSv4.x.

By specifying optional parameters, you can determine important information about each lock type. See the man page for the command for more information.

### Step

1. Display information about locks by using the `vserver locks show` command.

### Examples

The following example displays summary information for an NFSv4 lock on a file with the path `/vol1/file1`. The sharelock access mode is `write-deny_none`, and the lock was granted with write delegation:

```
cluster1::> vserver locks show

Vserver: vs0
Volume Object Path LIF Protocol Lock Type Client
----- -----
----- -----
vol1 /vol1/file1 lif1 nfsv4 share-level -
 Sharelock Mode: write-deny_none
 delegation -
 Delegation Type: write
```

The following example displays detailed oplock and sharelock information about the SMB lock on a file with the path `/data2/data2_2/intro.pptx`. A durable handle is granted on the file with a share lock access mode of `write-deny_none` to a client with an IP address of 10.3.1.3. A lease oplock is granted with a batch oplock level:

```
cluster1::> vserver locks show -instance -path /data2/data2_2/intro.pptx

Vserver: vs1
Volume: data2_2
Logical Interface: lif2
```

```
Object Path: /data2/data2_2/intro.pptx
Lock UUID: 553cf484-7030-4998-88d3-1125adbba0b7

## Break locks

When file locks are preventing client access to files, you can display information about currently held locks, and then break specific locks. Examples of scenarios in which you might need to break locks include debugging applications.

### About this task

The `vserver locks break` command is available only at the advanced privilege level and higher. The man page for the command contains detailed information.

### Steps

1. To find the information you need to break a lock, use the `vserver locks show` command.

The man page for the command contains detailed information.

2. Set the privilege level to advanced: `set -privilege advanced`
3. Perform one of the following actions:

| If you want to break a lock by specifying...       | Enter the command...                                                                           |
|----------------------------------------------------|------------------------------------------------------------------------------------------------|
| The SVM name, volume name, LIF name, and file path | <code>vserver locks break -vserver vserver_name -volume volume_name -path path -lif lif</code> |
| The lock ID                                        | <code>vserver locks break -lockid UUID</code>                                                  |

4. Return to the admin privilege level: `set -privilege admin`

## Monitor SMB activity

### Display SMB session information

You can display information about established SMB sessions, including the SMB connection and session ID and the IP address of the workstation using the session. You can display information about the session's SMB protocol version and continuously available protection level, which helps you identify whether the session supports nondisruptive operations.

### About this task

You can display information for all of the sessions on your SVM in summary form. However, in many cases, the amount of output that is returned is large. You can customize what information is displayed in the output by specifying optional parameters:

- You can use the optional `-fields` parameter to display output about the fields you choose.

You can enter `-fields ?` to determine what fields you can use.

- You can use the `-instance` parameter to display detailed information about established SMB sessions.
- You can use the `-fields` parameter or the `-instance` parameter either alone or in combination with other optional parameters.

## Step

1. Perform one of the following actions:

| If you want to display SMB session information... | Enter the following command...                                                                                                                                                                                                                                                                                       |
|---------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| For all sessions on the SVM in summary form       | <code>vserver cifs session show -vserver vserver_name</code>                                                                                                                                                                                                                                                         |
| On a specified connection ID                      | <code>vserver cifs session show -vserver vserver_name -connection-id integer</code>                                                                                                                                                                                                                                  |
| From a specified workstation IP address           | <code>vserver cifs session show -vserver vserver_name -address workstation_IP_address</code>                                                                                                                                                                                                                         |
| On a specified LIF IP address                     | <code>vserver cifs session show -vserver vserver_name -lif-address LIF_IP_address</code>                                                                                                                                                                                                                             |
| On a specified node                               | <code>vserver cifs session show -vserver vserver_name -node {node_name local}</code>                                                                                                                                                                                                                                 |
| From a specified Windows user                     | <code>vserver cifs session show -vserver vserver_name -windows-user domain_name\\user_name</code>                                                                                                                                                                                                                    |
| With a specified authentication mechanism         | <code>vserver cifs session show -vserver vserver_name -auth-mechanism {NTLMv1 NTLMv2 Kerberos Anonymous}</code>                                                                                                                                                                                                      |
| With a specified protocol version                 | <code>vserver cifs session show -vserver vserver_name -protocol-version {SMB1 SMB2 SMB2_1 SMB3 SMB3_1}</code>                                                                                                                                                                                                        |
|                                                   |  Continuously available protection and SMB Multichannel are available only on SMB 3.0 and later sessions. To view their status on all qualifying sessions, you should specify this parameter with the value set to SMB3 or later. |

| If you want to display SMB session information...           | Enter the following command...                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
|-------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| With a specified level of continuously available protection | <pre>vserver cifs session show -vserver vserver_name -continuously-available {No Yes Partial}</pre> <p> If the continuously available status is Partial, this means that the session contains at least one open continuously available file, but the session has some files that are not open with continuously available protection. You can use the vserver cifs sessions file show command to determine which files on the established session are not open with continuously available protection.</p> |
| With a specified SMB signing session status                 | <pre>vserver cifs session show -vserver vserver_name -is-session-signed {true false}</pre>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |

## Examples

The following command displays session information for the sessions on SVM vs1 established from a workstation with IP address 10.1.1.1:

```
cluster1::> vserver cifs session show -address 10.1.1.1
Node: node1
Vserver: vs1
Connection Session
ID ID Workstation Windows User Open Idle
----- ----- -----
3151272279,
3151272280,
3151272281 1 10.1.1.1 DOMAIN\joe 2 23s
```

The following command displays detailed session information for sessions with continuously available protection on SVM vs1. The connection was made by using the domain account.

```
cluster1::> vserver cifs session show -instance -continuously-available
Yes

 Node: node1
 Vserver: vs1
 Session ID: 1
 Connection ID: 3151274158
Incoming Data LIF IP Address: 10.2.1.1
 Workstation IP address: 10.1.1.2
 Authentication Mechanism: Kerberos
 Windows User: DOMAIN\SERVER1$
 UNIX User: pcuser
 Open Shares: 1
 Open Files: 1
 Open Other: 0
 Connected Time: 10m 43s
 Idle Time: 1m 19s
 Protocol Version: SMB3
Continuously Available: Yes
 Is Session Signed: false
 User Authenticated as: domain-user
 NetBIOS Name: -
SMB Encryption Status: Unencrypted
```

The following command displays session information on a session using SMB 3.0 and SMB Multichannel on SVM vs1. In the example, the user connected to this share from an SMB 3.0 capable client by using the LIF IP address; therefore, the authentication mechanism defaulted to NTLMv2. The connection must be made by using Kerberos authentication to connect with continuously available protection.

```
cluster1::> vserver cifs session show -instance -protocol-version SMB3

 Node: node1
 Vserver: vs1
 Session ID: 1
 **Connection IDs: 3151272607,31512726078,3151272609
 Connection Count: 3**
Incoming Data LIF IP Address: 10.2.1.2
 Workstation IP address: 10.1.1.3
Authentication Mechanism: NTLMv2
 Windows User: DOMAIN\administrator
 UNIX User: pcuser
 Open Shares: 1
 Open Files: 0
 Open Other: 0
 Connected Time: 6m 22s
 Idle Time: 5m 42s
 Protocol Version: SMB3
Continuously Available: No
 Is Session Signed: false
User Authenticated as: domain-user
 NetBIOS Name: -
SMB Encryption Status: Unencrypted
```

## Related information

[Displaying information about open SMB files](#)

**Display information about open SMB files**

You can display information about open SMB files, including the SMB connection and session ID, the hosting volume, the share name, and the share path. You can display information about a file's continuously available protection level, which is helpful in determining whether an open file is in a state that supports nondisruptive operations.

### About this task

You can display information about open files on an established SMB session. The displayed information is useful when you need to determine SMB session information for particular files within an SMB session.

For example, if you have an SMB session where some of the open files are open with continuously available protection and some are not open with continuously available protection (the value for the `-continuously-available` field in `vserver cifs session show` command output is `Partial`), you can determine which files are not continuously available by using this command.

You can display information for all open files on established SMB sessions on storage virtual machines (SVMs) in summary form by using the `vserver cifs session file show` command without any optional parameters.

However, in many cases, the amount of output returned is large. You can customize what information is displayed in the output by specifying optional parameters. This can be helpful when you want to view information for only a small subset of open files.

- You can use the optional `-fields` parameter to display output on the fields you choose.

You can use this parameter either alone or in combination with other optional parameters.

- You can use the `-instance` parameter to display detailed information about open SMB files.

You can use this parameter either alone or in combination with other optional parameters.

## Step

1. Perform one of the following actions:

| If you want to display open SMB files... | Enter the following command...                                                                               |
|------------------------------------------|--------------------------------------------------------------------------------------------------------------|
| On the SVM in summary form               | <code>vserver cifs session file show<br/>-vserver vserver_name</code>                                        |
| On a specified node                      | <code>vserver cifs session file show<br/>-vserver vserver_name -node<br/>{node_name local}</code>            |
| On a specified file ID                   | <code>vserver cifs session file show<br/>-vserver vserver_name -file-id integer</code>                       |
| On a specified SMB connection ID         | <code>vserver cifs session file show<br/>-vserver vserver_name -connection-id<br/>integer</code>             |
| On a specified SMB session ID            | <code>vserver cifs session file show<br/>-vserver vserver_name -session-id<br/>integer</code>                |
| On the specified hosting aggregate       | <code>vserver cifs session file show<br/>-vserver vserver_name -hosting<br/>-aggregate aggregate_name</code> |
| On the specified volume                  | <code>vserver cifs session file show<br/>-vserver vserver_name -hosting-volume<br/>volume_name</code>        |
| On the specified SMB share               | <code>vserver cifs session file show<br/>-vserver vserver_name -share<br/>share_name</code>                  |

| If you want to display open SMB files...                      | Enter the following command...                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
|---------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| On the specified SMB path                                     | <pre>vserver cifs session file show -vserver vserver_name -path path</pre>                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| With the specified level of continuously available protection | <pre>vserver cifs session file show -vserver vserver_name -continuously -available {No Yes}</pre> <p> If the continuously available status is No, this means that these open files are not capable of nondisruptively recovering from takeover and giveback. They also cannot recover from general aggregate relocation between partners in a high-availability relationship.</p>                                                                |
| With the specified reconnected state                          | <pre>vserver cifs session file show -vserver vserver_name -reconnected {No Yes}</pre> <p> If the reconnected state is No, the open file is not reconnected after a disconnection event. This can mean that the file was never disconnected, or that the file was disconnected and is not successfully reconnected. If the reconnected state is Yes, this means that the open file is successfully reconnected after a disconnection event.</p> |

There are additional optional parameters that you can use to refine the output results. See the man page for more information.

## Examples

The following example displays information about open files on SVM vs1:

```

cluster1::> vserver cifs session file show -vserver vs1
Node: node1
Vserver: vs1
Connection: 3151274158
Session: 1
File File Open Hosting Continuously
ID Type Mode Volume Share
----- ----- -----
41 Regular r data data Yes
Path: \mytest.rtf

```

The following example displays detailed information about open SMB files with file ID 82 on SVM vs1:

```

cluster1::> vserver cifs session file show -vserver vs1 -file-id 82
-instance

 Node: node1
 Vserver: vs1
 File ID: 82
 Connection ID: 104617
 Session ID: 1
 File Type: Regular
 Open Mode: rw
Aggregate Hosting File: agg1
 Volume Hosting File: data1
 CIFS Share: data1
 Path from CIFS Share: windows\win8\test\test.txt
 Share Mode: rw
 Range Locks: 1
Continuously Available: Yes
 Reconnected: No

```

## Related information

[Displaying SMB session information](#)

[Determine which statistics objects and counters are available](#)

Before you can obtain information about CIFS, SMB, auditing, and BranchCache hash statistics and monitor performance, you must know which objects and counters are available from which you can obtain data.

## Steps

1. Set the privilege level to advanced: `set -privilege advanced`
2. Perform one of the following actions:

| If you want to determine...         | Enter...                                           |
|-------------------------------------|----------------------------------------------------|
| Which objects are available         | statistics catalog object show                     |
| Specific objects that are available | statistics catalog object show object object_name  |
| Which counters are available        | statistics catalog counter show object object_name |

See the man pages for more information about which objects and counters are available.

3. Return to the admin privilege level: `set -privilege admin`

### Examples

The following command displays descriptions of selected statistic objects related to CIFS and SMB access in the cluster as seen at the advanced privilege level:

```

cluster1::> set -privilege advanced

Warning: These advanced commands are potentially dangerous; use them only
when directed to do so by support personnel.
Do you want to continue? {y|n}: y

cluster1::*> statistics catalog object show -object audit
 audit_ng CM object for exporting audit_ng
performance counters

cluster1::*> statistics catalog object show -object cifs
 cifs The CIFS object reports activity of the
 Common Internet File System protocol
 ...
cluster1::*> statistics catalog object show -object nblade_cifs
 nblade_cifs The Common Internet File System (CIFS)
 protocol is an implementation of the
Server
 ...
cluster1::*> statistics catalog object show -object smb1
 smb1 These counters report activity from the

cluster1::*> statistics catalog object show -object smb2
 smb2 These counters report activity from the
 SMB2/SMB3 revision of the protocol. For
 ...
cluster1::*> statistics catalog object show -object hashd
 hashd The hashd object provides counters to
measure
 the performance of the BranchCache hash
daemon.
cluster1::*> set -privilege admin

```

The following command displays information about some of the counters for the `cifs` object as seen at the advanced privilege level:

This example does not display all of the available counters for the `cifs` object; output is truncated.

```
cluster1::> set -privilege advanced

Warning: These advanced commands are potentially dangerous; use them only
when directed to do so by support personnel.
Do you want to continue? {y|n}: y
```

```
cluster1::*> statistics catalog counter show -object cifs
```

Object: cifs

| Counter              | Description                                                                  |
|----------------------|------------------------------------------------------------------------------|

## Related information

[Displaying statistics](#)

## Display statistics

You can display various statistics, including statistics about CIFS and SMB, auditing, and BranchCache hashes, to monitor performance and diagnose issues.

### Before you begin

You must have collected data samples by using the `statistics start` and `statistics stop` commands before you can display information about objects.

### Steps

1. Set the privilege level to advanced: `set -privilege advanced`
2. Perform one of the following actions:

| If you want to display statistics for... | Enter...                                         |
|------------------------------------------|--------------------------------------------------|
| All versions of SMB                      | <code>statistics show -object cifs</code>        |
| SMB 1.0                                  | <code>statistics show -object smb1</code>        |
| SMB 2.x and SMB 3.0                      | <code>statistics show -object smb2</code>        |
| CIFS subsystem of the node               | <code>statistics show -object nblade_cifs</code> |
| Multiprotocol audit                      | <code>statistics show -object audit_ng</code>    |
| BranchCache hash service                 | <code>statistics show -object hashd</code>       |
| Dynamic DNS                              | <code>statistics show -object ddns_update</code> |

See the man page for each command for more information.

3. Return to the admin privilege level: `set -privilege admin`

### Use offline files to allow caching of files for offline use

#### Use offline files to allow caching of files for offline use overview

ONTAP supports the Microsoft Offline Files feature, or *client-side caching*, which allows files to be cached on the local host for offline use. Users can use the offline files functionality to continue working on files even when they are disconnected from the network.

You can specify whether Windows user documents and programs are automatically cached on a share or whether the files must be manually selected for caching. Manual caching is enabled by default for new shares. The files that are made available offline are synchronized to the Windows client's local disk. Synchronization occurs when network connectivity to a specific storage system share is restored.

Because offline files and folders retain the same access permissions as the version of the files and folders saved on the CIFS server, the user must have sufficient permissions on the files and folders saved on the CIFS server to perform actions on the offline files and folders.

When the user and someone else on the network make changes to the same file, the user can save the local version of the file to the network, keep the other version, or save both. If the user keeps both versions, a new file with the local user's changes is saved locally and the cached file is overwritten with changes from the version of the file saved on the CIFS server.

You can configure offline files on a share-by-share basis by using share configuration settings. You can choose one of the four offline folder configurations when you create or modify shares:

- No caching

Disables client-side caching for the share. Files and folders are not automatically cached locally on clients and users cannot choose to cache files or folders locally.

- Manual caching

Enables manual selection of files to be cached on the share. This is the default setting. By default, no files or folders are cached on the local client. Users can choose which files and folders they want to cache locally for offline use.

- Automatic document caching

Enables user documents to be automatically cached on the share. Only files and folders that are accessed are cached locally.

- Automatic program caching

Enables programs and user documents to be automatically cached on the share. Only files, folders, and programs that are accessed are cached locally. Additionally, this setting allows the client to run locally cached executables even when connected to the network.

For more information about configuring offline files on Windows servers and clients, consult the Microsoft TechNet Library.

#### **Requirements for using offline files**

Before you can use the Microsoft Offline Files feature with your CIFS server, you need to know which versions of ONTAP and SMB and which Windows clients support the feature.

#### **ONTAP version requirements**

ONTAP releases support offline files.

#### **SMB protocol version requirements**

For storage virtual machine (SVM), ONTAP supports offline files on all versions of SMB.

#### **Windows client requirements**

The Windows client must support the offline files.

For the latest information about which Windows clients supports the Offline Files feature, see the Interoperability Matrix.

[mysupport.netapp.com/matrix](http://mysupport.netapp.com/matrix)

#### **Guidelines for deploying offline files**

There are some important guidelines you need to understand when you deploy offline files on home directory shares that have the `showsnapshot` share property set on home directories.

If the `showsnapshot` share property is set on a home directory share that has offline files configured, Windows clients cache all of the Snapshot copies under the `~snapshot` folder in the user's home directory.

Windows clients cache all of the Snapshot copies under the home directory if one or more of the following is true:

- The user makes the home directory available offline from the client.

The contents of the `~snapshot` folder in the home directory is included and made available offline.

- The user configures folder redirection to redirect a folder such as `My Documents` to the root of a home directory residing on the CIFS server share.

Some Windows clients might automatically make the redirected folder available offline. If the folder is redirected to the root of the home directory, the `~snapshot` folder is included in the cached offline content.

Offline file deployments where the ~snapshot folder is included in offline files should be avoided. The Snapshot copies in the ~snapshot folder contain all data on the volume at the point at which ONTAP created the Snapshot copy. Therefore, creating an offline copy of the ~snapshot folder consumes significant local storage on the client, consumes network bandwidth during offline files synchronization, and increases the time it takes to synchronize offline files.

#### Configure offline files support on SMB shares using the CLI

You can configure offline files support using the ONTAP CLI by specifying one of the four offline files setting when you create SMB shares or at any time by modifying existing SMB shares. Manual offline files support is the default setting.

#### About this task

When configuring offline files support, you can choose one of the following four offline files settings:

| Setting   | Description                                                                                                                                                                     |
|-----------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| none      | Disallows Windows clients from caching any files on this share.                                                                                                                 |
| manual    | Allows users on Windows clients to manually select files to be cached.                                                                                                          |
| documents | Allows Windows clients to cache user documents that are used by the user for offline access.                                                                                    |
| programs  | Allows Windows clients to cache programs that are used by the user for offline access. Clients can use the cached program files in offline mode even if the share is available. |

You can choose only one offline file setting. If you modify an offline files setting on an existing SMB share, the new offline files setting replaces the original setting. Other existing SMB share configuration settings and share properties are not removed or replaced. They remain in effect until they are explicitly removed or changed.

#### Steps

1. Perform the appropriate action:

| If you want to configure offline files on... | Enter the command...                                                                                                                         |
|----------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------|
| A new SMB share                              | <pre>vserver cifs share create -vserver vserver_name -share-name share_name -path path -offline-files {none manual documents programs}</pre> |

| If you want to configure offline files on... | Enter the command...                                                                                                            |
|----------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------|
| An existing SMB share                        | vserver cifs share modify -vserver<br>vserver_name -share-name share_name<br>-offline-files<br>{none manual documents programs} |

2. Verify that the SMB share configuration is correct: vserver cifs share show -vserver  
vserver\_name -share-name share\_name -instance

### Example

The following command creates an SMB share named "data1" with offline files set to documents:

```
cluster1::> vserver cifs share create -vserver vs1 -share-name data1 -path
/data1 -comment "Offline files" -offline-files documents

cluster1::> vserver cifs share show -vserver vs1 -share-name data1
-instance

 Vserver: vs1
 Share: data1
 CIFS Server NetBIOS Name: VS1
 Path: /data1
 Share Properties: oplocks
 browsable
 changenotify
 Symlink Properties: enable
 File Mode Creation Mask: -
 Directory Mode Creation Mask: -
 Share Comment: Offline files
 Share ACL: Everyone / Full Control
 File Attribute Cache Lifetime: -
 Volume Name: -
 Offline Files: documents
 Vscan File-Operations Profile: standard
 Maximum Tree Connections on Share: 4294967295
 UNIX Group for File Create: -
```

The following command modifies an existing SMB share named "data1" by changing the offline files setting to manual and adding values for the file and directory mode creation mask:

```
cluster1::> vserver cifs share modify -vserver vs1 -share-name data1
-offline-files manual -file-umask 644 -dir-umask 777

cluster1::> vserver cifs share show -vserver vs1 -share-name data1
-instance

 Vserver: vs1
 Share: data1
 CIFS Server NetBIOS Name: VS1
 Path: /data1
 Share Properties: oplocks
 browsable
 changenotify
 Symlink Properties: enable
 File Mode Creation Mask: 644
 Directory Mode Creation Mask: 777
 Share Comment: Offline files
 Share ACL: Everyone / Full Control
 File Attribute Cache Lifetime: -
 Volume Name: -
 Offline Files: manual
 Vscan File-Operations Profile: standard
 Maximum Tree Connections on Share: 4294967295
 UNIX Group for File Create: -
```

## Related information

[Adding or removing share properties on an existing SMB share](#)

[Configure offline files support on SMB shares by using the Computer Management MMC](#)

If you want to permit users to cache files locally for offline use, you can configure offline files support by using the Computer Management MMC (Microsoft Management Console).

## Steps

1. To open the MMC on your Windows server, in Windows Explorer, right-click the icon for the local computer, and then select **Manage**.
2. On the left panel, select **Computer Management**.
3. Select **Action > Connect to another computer**.  
The Select Computer dialog box appears.
4. Type the name of the CIFS server or click **Browse** to locate the CIFS server.

If the name of CIFS server is the same as the storage virtual machine (SVM) host name, type the SVM name. If the CIFS server name is different from the SVM host name, type the name of the CIFS server.

5. Click **OK**.
6. In the console tree, click **System Tools > Shared Folders**.
7. Click **Shares**.
8. In the results pane, right-click the share.
9. Click **Properties**.

Properties for the share you selected are displayed.

10. In the **General** tab, click **Offline Settings**.

The Offline Settings dialog box appears.

11. Configure the offline availability options as appropriate.
12. Click **OK**.

## Use roaming profiles to store user profiles centrally on a SMB server associated with the SVM

### Use roaming profiles to store user profiles centrally on a SMB server associated with the SVM overview

ONTAP supports storing Windows roaming profiles on a CIFS server associated with the storage virtual machine (SVM). Configuring user roaming profiles provides advantages to the user such as automatic resource availability regardless of where the user logs in. Roaming profiles also simplify the administration and management of user profiles.

Roaming user profiles have the following advantages:

- Automatic resource availability

A user's unique profile is automatically available when that user logs in to any computer on the network that is running Windows 8, Windows 7, Windows 2000, or Windows XP. Users do not need to create a profile on each computer they use on a network.

- Simplified computer replacement

Because all of the user's profile information is maintained separately on the network, a user's profile can be easily downloaded onto a new, replacement computer. When the user logs in to the new computer for the first time, the server copy of the user's profile is copied to the new computer.

### Requirements for using roaming profiles

Before you can use Microsoft's roaming profiles with your CIFS server, you need to know which versions of ONTAP and SMB and which Windows clients support the feature.

## ONTAP version requirements

ONTAP support roaming profiles.

## SMB protocol version requirements

For storage virtual machine (SVM), ONTAP supports roaming profiles on all versions of SMB.

## Windows client requirements

Before a user can use the roaming profiles, the Windows client must support the feature.

For the latest information about which Windows clients support roaming profiles, see the Interoperability Matrix.

### [NetApp Interoperability Matrix Tool](#)

#### Configure roaming profiles

If you want to automatically make a user's profile available when that user logs on to any computer on the network, you can configure roaming profiles through the Active Directory Users and Computers MMC snap-in. If you are configuring roaming profiles on Windows Server 2012, you can use the Active Directory Administration Center.

#### Steps

1. On the Windows server, open the Active Directory Users and Computers MMC (or the Active Directory Administration Center on Windows 2012 and later servers).
2. Locate the user for which you want to configure a roaming profile.
3. Right-click the user and click **Properties**.
4. On the **Profile** tab, enter the profile path to the share where you want to store the user's roaming profile, followed by %username%.

For example, a profile path might be the following: \\vs1.example.com\profiles\%username%. The first time a user logs in, %username% is replaced with the user's name.

In the path \\vs1.example.com\profiles\%username%, profiles is the share name of a share on storage virtual machine (SVM) vs1 that has Full Control rights for Everyone.

5. Click **OK**.

## Use folder redirection to store data on a SMB server

### Use folder redirection to store data on a SMB server overview

ONTAP supports Microsoft folder redirection, which enables users or administrators to redirect the path of a local folder to a location on the CIFS server. It appears as if redirected folders are stored on the local Windows client, even though the data is stored on an SMB share.

Folder redirection is intended mostly for organizations that have already deployed home directories, and that want to maintain compatibility with their existing home directory environment.

- Documents, Desktop, and Start Menu are examples of folders that you can redirect.
- Users can redirect folders from their Windows client.
- Administrators can centrally configure and manage folder redirection by configuring GPOs in Active Directory.
- If administrators have configured roaming profiles, folder redirection enables administrators to divide user data from profile data.
- Administrators can use folder redirection and offline files together to redirect data storage for local folders to the CIFS server, while allowing users to cache the content locally.

## Requirements for using folder redirection

Before you can use Microsoft's folder redirection with your CIFS server, you need to know which versions of ONTAP and SMB and which Windows clients support the feature.

### ONTAP version requirements

ONTAP support Microsoft folder redirection.

### SMB protocol version requirements

For storage virtual machine (SVM), ONTAP supports Microsoft's folder redirection on all versions of SMB.

### Windows client requirements

Before a user can use Microsoft's folder redirection, the Windows client must support the feature.

For the latest information about which Windows clients support folder redirection, see the Interoperability Matrix.

[mysupport.netapp.com/matrix](http://mysupport.netapp.com/matrix)

## Configure folder redirection

You can configure folder redirection using the Windows Properties window. The advantage to using this method is that the Windows user can configure folder redirection without assistance from the SVM administrator.

### Steps

1. In Windows Explorer, right-click the folder that you want to redirect to a network share.
2. Click **Properties**.

Properties for the share you selected are displayed.

3. In the **Shortcut** tab, click **Target** and specify the path to the network location where you want to redirect the selected folder.

For example, if you want to redirect a folder to the `data` folder in a home directory that is mapped to `Q:\`, specify `Q:\data` as the target.

4. Click **OK**.

For more information about configuring offline folders, consult the Microsoft TechNet Library.

[Microsoft TechNet Library: technet.microsoft.com/en-us/library/](http://technet.microsoft.com/en-us/library/)

## Access the `~snapshot` directory from Windows clients using SMB 2.x

The method that you use to access the `~snapshot` directory from Windows clients using SMB 2.x differs from the method used for SMB 1.0. You need to understand how to access the `~snapshot` directory when using SMB 2.x connections to successfully access data stored in Snapshot copies.

The SVM administrator controls whether users on Windows clients can view and access the `~snapshot` directory on a share by enabling or disabling the `showsnapshot` share property using commands from the `vserver cifs share properties` families.

When the `showsnapshot` share property is disabled, a user on a Windows client using SMB 2.x cannot view the `~snapshot` directory and cannot access Snapshot copies within the `~snapshot` directory, even when manually entering the path to the `~snapshot` directory or to specific Snapshot copies within the directory.

When the `showsnapshot` share property is enabled, a user on a Windows client using SMB 2.x still cannot view the `~snapshot` directory either at the root of the share or within any junction or directory below the root of the share. However, after connecting to a share, the user can access the hidden `~snapshot` directory by manually appending `\~snapshot` to the end of the share path. The hidden `~snapshot` directory is accessible from two entry points:

- At the root of the share
- At every junction point in the share space

The hidden `~snapshot` directory is not accessible from non-junction subdirectories within the share.

## Example

With the configuration shown in the following example, a user on a Windows client with an SMB 2.x connection to the “eng” share can access the `~snapshot` directory by manually appending `\~snapshot` to the share path at the root of the share and at every junction point in the path. The hidden `~snapshot` directory is accessible from the following three paths:

- `\vs1\eng\~snapshot`
- `\vs1\eng\projects1\~snapshot`
- `\vs1\eng\projects2\~snapshot`

```

cluster1::> volume show -vserver vs1 -fields volume,junction-path
vserver volume junction-path

vs1 vs1_root /
vs1 vs1_vol1 /eng
vs1 vs1_vol2 /eng/projects1
vs1 vs1_vol3 /eng/projects2

cluster1::> vserver cifs share show
Vserver Share Path Properties Comment ACL
----- ----- -----
vs1 eng /eng oplocks -
 changenotify
 browsable
 showsnapshot

```

## Recover files and folders using Previous Versions

### Recover files and folders using previous versions overview

The ability to use Microsoft Previous Versions is applicable to file systems that support Snapshot copies in some form and have them enabled. Snapshot technology is an integral part of ONTAP. Users can recover files and folders from Snapshot copies from their Windows client by using the Microsoft Previous Versions feature.

Previous Versions functionality provides a method for users to browse through the Snapshot copies or to restore data from a Snapshot copy without a storage administrator's intervention. Previous Versions is not configurable. It is always enabled. If the storage administrator has made Snapshot copies available on a share, then the user can use Previous Versions to perform the following tasks:

- Recover files that were accidentally deleted.
- Recover from accidentally overwriting a file.
- Compare versions of file while working.

The data stored in Snapshot copies is read-only. Users must save a copy of a file to another location to make any changes to the file. Snapshot copies are periodically deleted; therefore, users need to create copies of files contained in Previous Versions if they want to indefinitely retain a previous version of a file.

### Requirements for using Microsoft Previous Versions

Before you can use Previous Versions with your CIFS server, you need to know which versions of ONTAP and SMB, and which Windows clients, support it. You also need to know about the Snapshot copy setting requirement.

### ONTAP version requirements

Supports Previous Versions.

## SMB protocol version requirements

For storage virtual machine (SVM), ONTAP supports Previous Versions on all versions of SMB.

## Windows client requirements

Before a user can use Previous Versions to access data in Snapshot copies, the Windows client must support the feature.

For the latest information about which Windows clients support Previous Versions, see the Interoperability Matrix.

[NetApp Interoperability Matrix Tool](#)

## Requirements for Snapshot copy settings

To use Previous Versions to access data in Snapshot copies, an enabled Snapshot policy must be associated to the volume containing the data, clients must be able to access to the Snapshot data, and Snapshot copies must exist.

### Use the Previous Versions tab to view and manage Snapshot copy data

Users on Windows client machines can use the Previous Versions tab on the Windows Properties window to restore data stored in Snapshot copies without needing to involve the storage virtual machine (SVM) administrator.

#### About this task

You can only use the Previous Versions tab to view and manage data in Snapshot copies of data stored on the SVM if the administrator has enabled Snapshot copies on the volume containing the share, and if the administrator configures the share to show Snapshot copies.

#### Steps

1. In Windows Explorer, display the contents of the mapped drive of the data stored on the CIFS server.
2. Right-click the file or folder in the mapped network drive whose Snapshot copies you want to view or manage.
3. Click **Properties**.

Properties for the file or folder you selected are displayed.

4. Click the **Previous Versions** tab.

A list of available Snapshot copies of the selected file or folder is displayed in the **Folder versions:** box. The listed Snapshot copies are identified by the Snapshot copy name prefix and the creation timestamp.

5. In the **Folder versions:** box, right-click the copy of the file or folder that you want to manage.
6. Perform the appropriate action:

| If you want to...                 | Do the following... |
|-----------------------------------|---------------------|
| View data from that Snapshot copy | Click <b>Open</b> . |

| If you want to...                             | Do the following... |
|-----------------------------------------------|---------------------|
| Create a copy of data from that Snapshot copy | Click <b>Copy</b> . |

Data in Snapshot copies is read-only. If you want to make modifications to files and folders listed in the Previous Versions tab, you must save a copy of the files and folders that you want to modify to a writable location and make modifications to the copies.

7. After you finish managing Snapshot data, close the **Properties** dialog box by clicking **OK**.

For more information about using the Previous Versions tab to view and manage Snapshot data, consult the Microsoft TechNet Library.

## Related information

[Microsoft TechNet Library: technet.microsoft.com/en-us/library/](http://technet.microsoft.com/en-us/library/)

### Determine whether Snapshot copies are available for Previous Versions use

You can view Snapshot copies from the Previous Versions tab only if an enabled Snapshot policy is applied to the volume containing the share, and if the volume configuration allows access to Snapshot copies. Determining Snapshot copy availability is helpful when assisting a user with Previous Versions access.

#### Steps

1. Determine whether the volume on which the share data resides has automatic Snapshot copies enabled and whether clients have access to Snapshot directories: `volume show -vserver vserver-name -volume volume-name -fields vserver, volume, snapdir-access, snapshot-policy, snapshot-count`

The output displays what Snapshot policy is associated with the volume, whether client Snapshot directory access is enabled, and the number of available Snapshot copies.

2. Determine whether the associated Snapshot policy is enabled: `volume snapshot policy show -policy policy-name`
3. List the available Snapshot copies: `volume snapshot show -volume volume_name`

For more information about configuring and managing Snapshot policies and Snapshot schedules, see [Data Protection](#).

#### Example

The following example displays information about Snapshot policies associated with the volume named "data1" that contains the shared data and available Snapshot copies on "data1".

```

cluster1::> volume show -vserver vs1 -volume data1 -fields
vserver,volume,snapshot-policy,snapdir-access,snapshot-count
vserver volume snapdir-access snapshot-policy snapshot-count

vs1 data1 true default 10

cluster1::> volume snapshot policy show -policy default
Vserver: cluster1
 Number of Is
Policy Name Schedules Enabled Comment

default 3 true Default policy with hourly, daily &
weekly schedules.
 Schedule Count Prefix SnapMirror Label

 hourly 6 hourly -
 daily 2 daily daily
 weekly 2 weekly weekly

cluster1::> volume snapshot show -volume data1
 ---Blocks---
Vserver Volume Snapshot State Size Total% Used%

vs1 data1
 weekly.2012-12-16_0015 valid 408KB 0% 1%
 daily.2012-12-22_0010 valid 420KB 0% 1%
 daily.2012-12-23_0010 valid 192KB 0% 0%
 weekly.2012-12-23_0015 valid 360KB 0% 1%
 hourly.2012-12-23_1405 valid 196KB 0% 0%
 hourly.2012-12-23_1505 valid 196KB 0% 0%
 hourly.2012-12-23_1605 valid 212KB 0% 0%
 hourly.2012-12-23_1705 valid 136KB 0% 0%
 hourly.2012-12-23_1805 valid 200KB 0% 0%
 hourly.2012-12-23_1905 valid 184KB 0% 0%

```

[Creating a Snapshot configuration to enable Previous Versions access](#)

[Data protection](#)

**Create a Snapshot configuration to enable Previous Versions access**

The Previous Versions functionality is always available, provided that client access to Snapshot copies is enabled and provided that Snapshot copies exist. If your Snapshot copy configuration does not meet these requirements, you can create a Snapshot copy configuration that does.

## Steps

1. If the volume containing the share to which you want to allow Previous Versions access does not have an associated Snapshot policy, associate a Snapshot policy to the volume and enable it by using the `volume modify` command.

For more information about using the `volume modify` command, see the man pages.

2. Enable access to the Snapshot copies by using the `volume modify` command to set the `-snap-dir` option to `true`.

For more information about using the `volume modify` command, see the man pages.

3. Verify that Snapshot policies are enabled and that access to Snapshot directories is enabled by using the `volume show` and `volume snapshot policy show` commands.

For more information about using the `volume show` and `volume snapshot policy show` commands, see the man pages.

For more information about configuring and managing Snapshot policies and Snapshot schedules, see [Data Protection](#).

### Guidelines for restoring directories that contain junctions

There are certain guidelines you should keep in mind when using Previous Versions to restore folders that contain junction points.

When using Previous Versions to restore folders that have child folders that are junction points, the restore can fail with an `Access Denied` error.

You can determine whether the folder that you are attempting to restore contains a junction by using the `vol show` command with the `-parent` option. You can also use the `vserver security trace` commands to create detailed logs about file and folder access issues.

## Deploy SMB server-based services

### Manage home directories

#### How ONTAP enables dynamic home directories

ONTAP home directories enable you to configure an SMB share that maps to different directories based on the user that connects to it and a set of variables. Instead of creating separate shares for each user, you can configure one share with a few home directory parameters to define a user's relationship between an entry point (the share) and the home directory (a directory on the SVM).

A user who is logged in as a guest user does not have a home directory and cannot access other users' home directories. There are four variables that determine how a user is mapped to a directory:

- **Share name**

This is the name of the share that you create to which the user connects. You must set the home directory property for this share.

The share name can use the following dynamic names:

- %w (the user's Windows user name)
- %d (the user's Windows domain name)
- %u (the user's mapped UNIX user name)

To make the share name unique across all home directories, the share name must contain either the %w or the %u variable. The share name can contain both the %d and the %w variable (for example, %d /%w), or the share name can contain a static portion and a variable portion (for example, home\_%w).

- **Share path**

This is the relative path, which is defined by the share and is therefore associated with one of the share names, that is appended to each search path to generate the user's entire home directory path from the root of the SVM. It can be static (for example, home), dynamic (for example, %w), or a combination of the two (for example, eng/%w).

- **Search paths**

This is the set of absolute paths from the root of the SVM that you specify that directs the ONTAP search for home directories. You can specify one or more search paths by using the vserver cifs homedirectory search-path add command. If you specify multiple search paths, ONTAP tries them in the order specified until it finds a valid path.

- **Directory**

This is the user's home directory that you create for the user. The directory name is usually the user's name. You must create the home directory in one of the directories that are defined by the search paths.

As an example, consider the following setup:

- User: John Smith
- User domain: acme
- User name: jsmith
- SVM name: vs1
- Home directory share name #1: home\_%w - share path: %w
- Home directory share name #2: %w - share path: %d/%w
- Search path #1: /vol0/home/home
- Search path #2: /vol1/home/home
- Search path #3: /vol2/home/home
- Home directory: /vol1/home/home/jsmith

Scenario 1: The user connects to \\vs1\home\_jsmith. This matches the first home directory share name and generates the relative path jsmith. ONTAP now searches for a directory named jsmith by checking each search path in order:

- /vol0/home/home/jsmith does not exist; moving on to search path #2.
- /vol1/home/home/jsmith does exist; therefore, search path #3 is not checked; the user is now connected to his home directory.

Scenario 2: The user connects to \\vs1\jsmith. This matches the second home directory share name and generates the relative path acme/jsmith. ONTAP now searches for a directory named acme/jsmith by checking each search path in order:

- /vol0/home/home/acme/jsmith does not exist; moving on to search path #2.
- /vol1/home/home/acme/jsmith does not exist; moving on to search path #3.
- /vol2/home/home/acme/jsmith does not exist; the home directory does not exist; therefore, the connection fails.

## Home directory shares

### Add a home directory share

If you want to use the SMB home directory feature, you must add at least one share with the home directory property included in the share properties.

#### About this task

You can create a home directory share at the time you create the share by using the vserver cifs share create command, or you can change an existing share into a home directory share at any time by using the vserver cifs share modify command.

To create a home directory share, you must include the homedirectory value in the -share-properties option when you create or modify a share. You can specify the share name and share path using variables that are dynamically expanded when users connect to their home directories. Available variables that you can use in the path are %w, %d, and %u, corresponding to the Windows user name, domain, and mapped UNIX user name, respectively.

#### Steps

1. Add a home directory share:

```
vserver cifs share create -vserver vserver_name -share-name share_name -path path -share-properties homedirectory[,...]
```

-vserver vserver specifies the CIFS-enabled storage virtual machine (SVM) on which to add the search path.

-share-name share-name specifies the home directory share name.

In addition to containing one of the required variables, if the share name contains one of the literal strings %w, %u, or %d, you must precede the literal string with a % (percent) character to prevent ONTAP from treating the literal string as a variable (for example, %%w).

- The share name must contain either the %w or the %u variable.

- The share name can additionally contain the %d variable (for example, %d/%w) or a static portion in the share name (for example, home1\_%w).
- If the share is used by administrators to connect to other users' home directories or to permit users to connect to other users' home directories, the dynamic share name pattern must be preceded by a tilde (~).

The vserver cifs home-directory modify is used to enable this access by setting the `-is-home-dirs-access-for-admin-enabled` option to true) or by setting the advanced option `-is-home-dirs-access-for-public-enabled` to true.

`-path path` specifies the relative path to the home directory.

`-share-properties homedirectory[,...]` specifies the share properties for that share. You must specify the homedirectory value. You can specify additional share properties using a comma delimited list.

1. Verify that you successfully added the home directory share by using the vserver cifs share show command.

### Example

The following command creates a home directory share named %w. The oplocks, browsable, and changenotify share properties are set in addition to setting the homedirectory share property.

This example does not display output for all of the shares on the SVM. Output is truncated.

```
cluster1::> vserver cifs share create -vserver vs1 -share-name %w -path %w
-share-properties oplocks,browsable,changedirectory,homedirectory
```

| Vserver | Share | Path | Properties                                               | Comment | ACL             |
|---------|-------|------|----------------------------------------------------------|---------|-----------------|
| vs1     | %w    | %w   | oplocks<br>browsable<br>changedirectory<br>homedirectory | -       | Everyone / Full |
| Control |       |      |                                                          |         |                 |

[Managing accessibility to users' home directories](#)

### Home directory shares require unique user names

Be careful to assign unique user names when creating home directory shares using the %w (Windows user name) or %u (UNIX user name) variables to generate shares dynamically. The share name is mapped to your user name.

Two problems can occur when a static share's name and a user's name are the same:

- When the user lists the shares on a cluster using the `net view` command, two shares with the same user name are displayed.
- When the user connects to that share name, the user is always connected to the static share and cannot access the home directory share with the same name.

For example, there is a share named "administrator" and you have an "administrator" Windows user name. If you create a home directory share and connect to that share, you get connected to the "administrator" static share, not to your "administrator" home directory share.

You can resolve the issue with duplicate share names by following any of these steps:

- Renaming the static share so that it no longer conflicts with the user's home directory share.
- Giving the user a new user name so that it no longer conflicts with the static share name.
- Creating a CIFS home directory share with a static name such as "home" instead of using the `%w` parameter to avoid conflicts with the share names.

### **What happens to static home directory share names after upgrading**

Home directory share names must contain either the `%w` or the `%u` dynamic variable. You should be aware of what happens to existing static home directory share names after upgrading to a version of ONTAP with the new requirement.

If your home directory configuration contains static share names and you upgrade to ONTAP, the static home directory share names are not changed and are still valid. However, you cannot create any new home directory shares that do not contain either the `%w` or `%u` variable.

Requiring that one of these variables is included in the user's home directory share name ensures that every share name is unique across the home directory configuration. If desired, you can change the static home directory share names to names that contain either the `%w` or `%u` variable.

#### **Add a home directory search path**

If you want to use ONTAP SMB home directories, you must add at least one home directory search path.

#### **About this task**

You can add a home directory search path by using the `vserver cifs home-directory search-path add` command.

The `vserver cifs home-directory search-path add` command checks the path specified in the `-path` option during command execution. If the specified path does not exist, the command generates a message prompting for whether you want to continue. You choose `y` or `n`. If you choose `y` to continue, ONTAP creates the search path. However, you must create the directory structure before you can use the search path in the home directory configuration. If you choose not to continue, the command fails; the search path is not created. You can then create the path directory structure and rerun the `vserver cifs home-directory search-path add` command.

#### **Steps**

1. Add a home directory search path: `vserver cifs home-directory search-path add -vserver`

- ```
vserver -path path
```
2. Verify that you successfully added the search path using the `vserver cifs home-directory search-path show` command.

Example

The following example adds the path `/home1` to the home directory configuration on SVM `vs1`.

```
cluster::> vserver cifs home-directory search-path add -vserver vs1 -path /home1

vs1::> vserver cifs home-directory search-path show
Vserver      Position Path
-----
vs1          1           /home1
```

The following example attempts to add the path `/home2` to the home directory configuration on SVM `vs1`. The path does not exist. The choice is made to not continue.

```
cluster::> vserver cifs home-directory search-path add -vserver vs1 -path /home2
Warning: The specified path "/home2" does not exist in the namespace
belonging to Vserver "vs1".
Do you want to continue? {y|n}: n
```

[Adding a home directory share](#)

Create a home directory configuration using the %w and %d variables

You can create a home directory configuration using the `%w` and `%d` variables. Users can then connect to their home share using dynamically created shares.

Steps

1. Create a qtree to contain user's home directories: `volume qtree create -vserver vserver_name -qtree-path qtree_path`
2. Verify that the qtree is using the correct security style: `volume qtree show`
3. If the qtree is not using the desired security style, change the security style using the `volume qtree security` command.
4. Add a home directory share: `vserver cifs share create -vserver vserver -share-name %w -path %d/%w -share-properties homedirectory\[, . . . \]`

`-vserver vserver` specifies the CIFS-enabled storage virtual machine (SVM) on which to add the search path.

`-share-name %w` specifies the home directory share name. ONTAP dynamically creates the share name

as each user connects to their home directory. The share name will be of the form *windows_user_name*.

-path %d/%w specifies the relative path to the home directory. The relative path is dynamically created as each user connects to their home directory and will be of the form *domain/windows_user_name*.

-share-properties homedirectory[, ...]+ specifies the share properties for that share. You must specify the *homedirectory* value. You can specify additional share properties using a comma delimited list.

5. Verify that the share has the desired configuration using the `vserver cifs share show` command.
6. Add a home directory search path: `vserver cifs home-directory search-path add -vserver vserver -path path`

-vserver vserver-name specifies the CIFS-enabled SVM on which to add the search path.

-path path specifies the absolute directory path to the search path.

7. Verify that you successfully added the search path using the `vserver cifs home-directory search-path show` command.
8. For users with a home directory, create a corresponding directory in the qtree or volume designated to contain home directories.

For example, if you created a qtree with the path of `/vol/vol1/users` and the user name whose directory you want to create is `mydomain\user1`, you would create a directory with the following path: `/vol/vol1/users/mydomain/user1`.

If you created a volume named "home1" mounted at `/home1`, you would create a directory with the following path: `/home1/mydomain/user1`.

9. Verify that a user can successfully connect to the home share either by mapping a drive or connecting using the UNC path.

For example, if user `mydomain\user1` wants to connect to the directory created in Step 8 that is located on SVM `vs1`, `user1` would connect using the UNC path `\vs1\user1`.

Example

The commands in the following example create a home directory configuration with the following settings:

- The share name is `%w`.
- The relative home directory path is `%d/%w`.
- The search path that is used to contain the home directories, `/home1`, is a volume configured with NTFS security style.
- The configuration is created on SVM `vs1`.

You can use this type of home directory configuration when users access their home directories from Windows hosts. You can also use this type of configuration when users access their home directories from Windows and UNIX hosts and the file system administrator uses Windows-based users and groups to control access to the file system.

```
cluster::> vserver cifs share create -vserver vs1 -share-name %w -path  
%d/%w -share-properties oplocks,browsable,changenotify,homedirectory
```

```
cluster::> vserver cifs share show -vserver vs1 -share-name %w
```

```
          Vserver: vs1  
          Share: %w  
CIFS Server NetBIOS Name: VS1  
          Path: %d/%w  
Share Properties: oplocks  
                  browsable  
                  changenotify  
                  homedirectory  
Symlink Properties: enable  
File Mode Creation Mask: -  
Directory Mode Creation Mask: -  
Share Comment: -  
Share ACL: Everyone / Full Control  
File Attribute Cache Lifetime: -  
Volume Name: -  
Offline Files: manual  
Vscan File-Operations Profile: standard
```

```
cluster::> vserver cifs home-directory search-path add -vserver vs1 -path  
/home1
```

```
cluster::> vserver cifs home-directory search-path show
```

Vserver	Position	Path
vs1	1	/home1

Related information

[Configuring home directories using the %u variable](#)

[Additional home directory configurations](#)

[Displaying information about an SMB user's home directory path](#)

Configure home directories using the %u variable

You can create a home directory configuration where you designate the share name using the %w variable but you use the %u variable to designate the relative path to the home directory share. Users can then connect to their home share using dynamically shares created using their Windows user name without being aware of the actual name or path of the home directory.

Steps

1. Create a qtree to contain user's home directories: `volume qtree create -vserver vserver_name -qtree-path qtree_path`
2. Verify that the qtree is using the correct security style: `volume qtree show`
3. If the qtree is not using the desired security style, change the security style using the `volume qtree security` command.
4. Add a home directory share: `vserver cifs share create -vserver vserver -share-name %w -path %u -share-properties homedirectory ,...]`
-vserver vserver specifies the CIFS-enabled storage virtual machine (SVM) on which to add the search path.
-share-name %w specifies the home directory share name. The share name is dynamically created as each user connects to their home directory and is of the form *windows_user_name*.

You can also use the %u variable for the -share-name option. This creates a relative share path that uses the mapped UNIX user name.

-path %u specifies the relative path to the home directory. The relative path is created dynamically as each user connects to their home directory and is of the form *mapped_UNIX_user_name*.

The value for this option can contain static elements as well. For example, eng/%u.

-share-properties homedirectory\[, . . . \] specifies the share properties for that share. You must specify the homedirectory value. You can specify additional share properties using a comma delimited list.

5. Verify that the share has the desired configuration using the `vserver cifs share show` command.
6. Add a home directory search path: `vserver cifs home-directory search-path add -vserver vserver -path path`
-vserver vserver specifies the CIFS-enabled SVM on which to add the search path.
-path path specifies the absolute directory path to the search path.
7. Verify that you successfully added the search path using the `vserver cifs home-directory search-path show` command.
8. If the UNIX user does not exist, create the UNIX user using the `vserver services unix-user create` command.

The UNIX user name to which you map the Windows user name must exist before mapping the user.

9. Create a name mapping for the Windows user to the UNIX user using the following command: `vserver name-mapping create -vserver vserver_name -direction win-unix -priority integer -pattern windows_user_name -replacement unix_user_name`

If name mappings already exist that map Windows users to UNIX users, you do not have to perform the mapping step.

The Windows user name is mapped to the corresponding UNIX user name. When the Windows user connects to their home directory share, they connect to a dynamically created home directory with a share name that corresponds to their Windows user name without being aware that the directory name corresponds to the UNIX user name.

10. For users with a home directory, create a corresponding directory in the qtree or volume designated to contain home directories.

For example, if you created a qtree with the path of `/vol/vol1/users` and the mapped UNIX user name of the user whose directory you want to create is “`unixuser1`”, you would create a directory with the following path: `/vol/vol1/users/unixuser1`.

If you created a volume named “`home1`” mounted at `/home1`, you would create a directory with the following path: `/home1/unixuser1`.

11. Verify that a user can successfully connect to the home share either by mapping a drive or connecting using the UNC path.

For example, if user `mydomain\user1` maps to UNIX user `unixuser1` and wants to connect to the directory created in Step 10 that is located on SVM `vs1`, `user1` would connect using the UNC path `\vs1\user1`.

Example

The commands in the following example create a home directory configuration with the following settings:

- The share name is `%w`.
- The relative home directory path is `%u`.
- The search path that is used to contain the home directories, `/home1`, is a volume configured with UNIX security style.
- The configuration is created on SVM `vs1`.

You can use this type of home directory configuration when users access their home directories from both Windows hosts or Windows and UNIX hosts and the file system administrator uses UNIX-based users and groups to control access to the file system.

```
cluster::> vserver cifs share create -vserver vs1 -share-name %w -path %u  
-share-properties oplocks,browsable,changeNotify,homedirectory
```

```
cluster::> vserver cifs share show -vserver vs1 -share-name %u
```

```
          Vserver: vs1  
          Share: %w  
CIFS Server NetBIOS Name: VS1  
          Path: %u  
Share Properties: oplocks  
                  browsable  
                  changeNotify  
                  homedirectory  
Symlink Properties: enable  
File Mode Creation Mask: -  
Directory Mode Creation Mask: -  
Share Comment: -  
Share ACL: Everyone / Full Control  
File Attribute Cache Lifetime: -  
Volume Name: -  
Offline Files: manual  
Vscan File-Operations Profile: standard
```

```
cluster::> vserver cifs home-directory search-path add -vserver vs1 -path  
/home1
```

```
cluster::> vserver cifs home-directory search-path show -vserver vs1  
Vserver      Position Path  
-----  
vs1           1           /home1
```

```
cluster::> vserver name-mapping create -vserver vs1 -direction win-unix  
-position 5 -pattern user1 -replacement unixuser1
```

```
cluster::> vserver name-mapping show -pattern user1  
Vserver      Direction Position  
-----  
vs1          win-unix   5          Pattern: user1  
                           Replacement: unixuser1
```

Related information

[Creating a home directory configuration using the %w and %d variables](#)

[Additional home directory configurations](#)

[Displaying information about an SMB user's home directory path](#)

Additional home directory configurations

You can create additional home directory configurations using the %w, %d, and %u variables, which enables you to customize the home directory configuration to meet your needs.

You can create a number of home directory configurations using a combination of variables and static strings in the share names and search paths. The following table provides some examples illustrating how to create different home directory configurations:

Paths created when /vol1/user contains home directories...	Share command...
To create a share path \\vs1\~win_username that directs the user to /vol1/user/win_username	vserver cifs share create -share-name ~%w -path %w -share-properties oplocks,browsable,changeNotify,homedirectory
To create a share path \\vs1\win_username that directs the user to /vol1/user/domain/win_username	vserver cifs share create -share-name %w -path %d/%w -share-properties oplocks,browsable,changeNotify,homedirectory
To create a share path \\vs1\win_username that directs the user to /vol1/user/unix_username	vserver cifs share create -share-name %w -path %u -share-properties oplocks,browsable,changeNotify,homedirectory
To create a share path \\vs1\unix_username that directs the user to /vol1/user/unix_username	vserver cifs share create -share-name %u -path %u -share-properties oplocks,browsable,changeNotify,homedirectory

Commands for managing search paths

There are specific ONTAP commands for managing search paths for SMB home directory configurations. For example, there are commands for adding, removing, and displaying information about search paths. There is also a command for changing the search path order.

If you want to...	Use this command...
Add a search path	vserver cifs home-directory search-path add
Display search paths	vserver cifs home-directory search-path show

If you want to...	Use this command...
Change the search path order	vserver cifs home-directory search-path reorder
Remove a search path	vserver cifs home-directory search-path remove

See the man page for each command for more information.

Display information about an SMB user's home directory path

You can display an SMB user's home directory path on the storage virtual machine (SVM), which can be used if you have multiple CIFS home directory paths configured and you want to see which path holds the user's home directory.

Step

1. Display the home directory path by using the `vserver cifs home-directory show-user` command.

```
vserver cifs home-directory show-user -vserver vs1 -username user1
```

Vserver	User	Home Dir Path
vs1	user1	/home/user1

Related information

[Managing accessibility to users' home directories](#)

Manage accessibility to users' home directories

By default, a user's home directory can be accessed only by that user. For shares where the dynamic name of the share is preceded with a tilde (~), you can enable or disable access to users' home directories by Windows administrators or by any other user (public access).

Before you begin

Home directory shares on the storage virtual machine (SVM) must be configured with dynamic share names that are preceded with a tilde (~). The following cases illustrate share naming requirements:

Home directory share name	Example of command to connect to the share
~%d~%w	<code>net use * \\IPaddress\~domain~user/u:credentials</code>
~%w	<code>net use * \\IPaddress\~user/u:credentials</code>

Home directory share name	Example of command to connect to the share
~abc~%w	net use * \\IPaddress\abc~user/u:credentials

Step

1. Perform the appropriate action:

If you want to enable or disable access to users' home directories to...	Enter the following...
Windows administrators	vserver cifs home-directory modify -vserver vserver_name -is-home-dirs-access-for-admin-enabled {true false} The default is true.
Any user (public access)	<ol style="list-style-type: none"> a. Set the privilege level to advanced: set -privilege advanced b. Enable or disable access: vserver cifs home-directory modify -vserver vserver_name -is-home-dirs-access-for-public-enabled {true false} The default is false. c. Return to the admin privilege level: set -privilege admin

The following example enables public access to users' home directories:

```
set -privilege advanced
vserver cifs home-directory modify -vserver vs1 -is-home-dirs-access-for-public-enabled true
set -privilege admin
```

[Displaying information about an SMB user's home directory path](#)

Configure SMB client access to UNIX symbolic links

How ONTAP enables you to provide SMB client access to UNIX symbolic links

A symbolic link is a file that is created in a UNIX environment that contains a reference to another file or directory. If a client accesses a symbolic link, the client is redirected to the target file or directory to which the symbolic link refers. ONTAP supports relative and absolute symbolic links, including widelinks (absolute links with targets outside the local file system).

ONTAP provides SMB clients the ability to follow UNIX symbolic links that are configured on the SVM. This feature is optional, and you can configure it on a per-share basis, using the `-symlink-properties` option of the `vserver cifs share create` command, with one of the following settings:

- Enabled with read/write access
- Enabled with read-only access
- Disabled by hiding symbolic links from SMB clients
- Disabled with no access to symbolic links from SMB clients

If you enable symbolic links on a share, relative symbolic links work without further configuration.

If you enable symbolic links on a share, absolute symbolic links do not work right away. You must first create a mapping between the UNIX path of the symbolic link to the destination SMB path. When creating absolute symbolic link mappings, you can specify whether it is a local link or a *widelink*; widelinks can be links to file systems on other storage devices or links to file systems hosted in separate SVMs on the same ONTAP system. When you create a widelink, it must include the information for the client to follow; that is, you create a reparse point for the client to discover the directory junction point. If you create an absolute symbolic link to a file or directory outside of the local share but set the locality to local, ONTAP disallows access to the target.

 If a client attempts to delete a local symbolic link (absolute or relative), only the symbolic link is deleted, not the target file or directory. However, if a client attempts to delete a widelink, it might delete the actual target file or directory to which the widelink refers. ONTAP does not have control over this because the client can explicitly open the target file or directory outside the SVM and delete it.

- **Reparse points and ONTAP file system services**

A *reparse point* is an NTFS file system object that can be optionally stored on volumes along with a file. Reparse points provide SMB clients the ability to receive enhanced or extended file system services when working with NTFS style volumes. Reparse points consist of standard tags that identify the type of reparse point, and the content of the reparse point that can be retrieved by SMB clients for further processing by the client. Of the object types available for extended file system functionality, ONTAP implements support for NTFS symbolic links and directory junction points using reparse point tags. SMB clients that cannot understand the contents of a reparse point simply ignore it and don't provide the extended file system service that the reparse point might enable.

- **Directory junction points and ONTAP support for symbolic links**

Directory junction points are locations within a file system directory structure that can refer to alternate locations where files are stored, either on a different path (symbolic links) or a separate storage device (widelinks). ONTAP SMB servers expose directory junction points to Windows clients as reparse points, allowing capable clients to obtain reparse point contents from ONTAP when a directory junction point is traversed. They can thereby navigate and connect to different paths or storage devices as though they were part of the same file system.

- **Enabling widelink support using reparse point options**

The `-is-use-junctions-as-reparse-points-enabled` option is enabled by default in ONTAP 9. Not all SMB clients support widelinks, so the option to enable the information is configurable on a per-protocol version basis, allowing administrators to accommodate both supported and non-supported SMB clients. In ONTAP 9.2 and later releases, you must enable the option `-widelink-as-reparse-point-versions` for each client protocol that accesses the share using widelinks; the default is SMB1. In earlier releases, only widelinks accessed using the default SMB1 were reported, and systems using SMB2 or SMB3 were unable to access the widelinks.

For more information, see the Microsoft NTFS documentation.

Limits when configuring UNIX symbolic links for SMB access

You need to be aware of certain limits when configuring UNIX symbolic links for SMB access.

Limit	Description
45	Maximum length of the CIFS server name that you can specify when using an FQDN for the CIFS server name.  You can alternatively specify the CIFS server name as a NetBIOS name, which is limited to 15 characters.
80	Maximum length of the share name.
256	Maximum length of the UNIX path that you can specify when creating a symbolic link or when modifying an existing symbolic link's UNIX path. The UNIX path must start with a "/" (slash) and end with a "/". Both the beginning and ending slashes count as part of the 256-character limit.
256	Maximum length of the CIFS path that you can specify when creating a symbolic link or when modifying an existing symbolic link's CIFS path. The CIFS path must start with a "/" (slash) and end with a "/". Both the beginning and ending slashes count as part of the 256-character limit.

Related information

[Creating symbolic link mappings for SMB shares](#)

[Control automatic DFS advertisements in ONTAP with a CIFS server option](#)

A CIFS server option controls how DFS capabilities are advertised to SMB clients when connecting to shares. Because ONTAP uses DFS referrals when clients access symbolic links over SMB, you should be aware of what the impact is when disabling or enabling this option.

A CIFS server option determines whether the CIFS servers automatically advertise that they are DFS capable to SMB clients. By default, this option is enabled and the CIFS server always advertises that it is DFS capable to SMB clients (even when connecting to shares where access to symbolic links is disabled). If you want the CIFS server to advertise that it is DFS capable to clients only when they are connecting to shares where access to symbolic links is enabled, you can disable this option.

You should be aware of what happens when this option is disabled:

- The share configurations for symbolic links is unchanged.
- If the share parameter is set to allow symbolic link access (either read-write access or read-only access), the CIFS server advertises DFS capabilities to clients connecting to that share.

Client connections and access to symbolic links continue without interruption.

- If the share parameter is set to not allow symbolic link access (either by disabling access or if the value for the share parameter is null), the CIFS server does not advertise DFS capabilities to clients connecting to that share.

Because clients have cached information that the CIFS server is DFS capable and it is no longer advertising that it is, clients that are connected to shares where symbolic link access is disabled might not be able to access these shares after the CIFS server option is disabled. After the option is disabled, you might need to reboot clients that are connected to these shares, thus clearing the cached information.

These changes do not apply to SMB 1.0 connections.

Configure UNIX symbolic link support on SMB shares

You can configure UNIX symbolic link support on SMB shares by specifying a symbolic link share-property setting when you create SMB shares or at any time by modifying existing SMB shares. UNIX symbolic link support is enabled by default. You can also disable UNIX symbolic link support on a share.

About this task

When configuring UNIX symbolic link support for SMB shares, you can choose one of the following settings:

Setting	Description
enable (DEPRECATED*)	Specifies that symbolic links are enabled for read-write access.
read_only (DEPRECATED*)	Specifies that symlinks are enabled for read-only access. This setting does not apply to widelinks. Widelink access is always read-write.
hide (DEPRECATED*)	Specifies that SMB clients are prevented from seeing symlinks.
no-strict-security	Specifies that clients follow symlinks outside of share boundaries.
symlinks	Specifies that symlinks are enabled locally for read-write access. The DFS advertisements are not generated even if the CIFS option <code>is-advertise-dfs-enabled</code> is set to <code>true</code> . This is the default setting.

Setting	Description
symlinks-and-widelinks	Specifies that both local symlinks and widelinks for read-write access. The DFS advertisements are generated for both local symlink and widelinks even if the CIFS option <code>is-advertise-dfs-enabled</code> is set to false.
disable	Specifies that symlinks and widelinks are disabled. The DFS advertisements are not generated even if the CIFS option <code>is-advertise-dfs-enabled</code> is set to true.
"" (null, not set)	Disables symbolic links on the share.
- (not set)	Disables symbolic links on the share.

*The `enable`, `hide`, and `read-only` parameters are deprecated and may be removed in a future release of ONTAP.

Steps

1. Configure or disable symbolic link support:

If it is...	Enter...
A new SMB share	<code>vserver cifs share create -vserver vserver_name -share-name share_name -path path -symlink-properties {enable hide read-only " " - symlinks symlinks-and-widelinks disable},...</code>
An existing SMB share	<code>vserver cifs share modify -vserver vserver_name -share-name share_name -symlink-properties {enable hide read-only " " - symlinks symlinks-and-widelinks disable},...</code>

2. Verify that the SMB share configuration is correct: `vserver cifs share show -vserver vserver_name -share-name share_name -instance`

Example

The following command creates an SMB share named “data1” with the UNIX symbolic link configuration set to enable:

```

cluster1::> vserver cifs share create -vserver vs1 -share-name data1 -path
/data1 -symlink-properties enable

cluster1::> vserver cifs share show -vserver vs1 -share-name data1
-instance

          Vserver: vs1
          Share: data1
          CIFS Server NetBIOS Name: VS1
          Path: /data1
          Share Properties: oplocks

[Creating symbolic link mappings for SMB shares](#)

Create symbolic link mappings for SMB shares

You can create mappings of UNIX symbolic links for SMB shares. You can either create a relative symbolic link, which refers to the file or folder relative to its parent folder, or you can create an absolute symbolic link, which refers to the file or folder using an absolute path.

About this task

Widelinks are not accessible from Mac OS X clients if you use SMB 2.x. When a user attempts to connect to a share using widelinks from a Mac OS X client, the attempt fails. However, you can use widelinks with Mac OS X clients if you use SMB 1.

Steps

1. To create symbolic link mappings for SMB shares: `vserver cifs symlink create -vserver virtual_server_name -unix-path path -share-name share_name -cifs-path path [-cifs-server server_name] [-locality {local|free|widelink}] [-home-directory {true|false}]`
`-vserver virtual_server_name` specifies the storage virtual machine (SVM) name.

-unix-path path specifies the UNIX path. The UNIX path must begin with a slash (/) and must end with a slash (/).

-share-name share_name specifies the name of the SMB share to map.

-cifs-path path specifies the CIFS path. The CIFS path must begin with a slash (/) and must end with a slash (/).

-cifs-server server_name specifies the CIFS server name. The CIFS server name can be specified as a DNS name (for example, mynetwork.cifs.server.com), IP address, or NetBIOS name. The NetBIOS name can be determined by using the `vserver cifs show` command. If this optional parameter is not specified, the default value is the NetBIOS name of the local CIFS server.

-locality {local|free|widelink} specifies whether to create a local link, a free link or a wide symbolic link. A local symbolic link maps to the local SMB share. A free symbolic link can map anywhere on the local SMB server. A wide symbolic link maps to any SMB share on the network. If you do not specify this optional parameter, the default value is local.

-home-directory {true|false} specifies whether the target share is a home directory. Even though this parameter is optional, you must set this parameter to true when the target share is configured as a home directory. The default is false.

Example

The following command creates a symbolic link mapping on the SVM named vs1. It has the UNIX path /src/, the SMB share name “SOURCE”, the CIFS path /mycompany/source/, and the CIFS server IP address 123.123.123.123, and it is a widelink.

```
cluster1::> vserver cifs symlink create -vserver vs1 -unix-path /src/
-share-name SOURCE -cifs-path "/mycompany/source/" -cifs-server
123.123.123.123 -locality widelink
```

Commands for managing symbolic link mappings

There are specific ONTAP commands for managing symbolic link mappings.

If you want to...	Use this command...
Create a symbolic link mapping	<code>vserver cifs symlink create</code>
Display information about symbolic link mappings	<code>vserver cifs symlink show</code>
Modify a symbolic link mapping	<code>vserver cifs symlink modify</code>
Delete a symbolic link mapping	<code>vserver cifs symlink delete</code>

See the man page for each command for more information.

Use BranchCache to cache SMB share content at a branch office

Use BranchCache to cache SMB share content at a branch office overview

BranchCache was developed by Microsoft to enable caching of content on computers local to requesting clients. ONTAP implementation of BranchCache can reduce wide-area network (WAN) utilization and provide improved access response time when users in a branch office access content stored on storage virtual machines (SVMs) using SMB.

If you configure BranchCache, Windows BranchCache clients first retrieve content from the SVM and then cache the content on a computer within the branch office. If another BranchCache-enabled client in the branch office requests the same content, the SVM first authenticates and authorizes the requesting user. The SVM then determines whether the cached content is still up-to-date and, if it is, sends the client metadata about the cached content. The client then uses the metadata to retrieve content directly from the locally based cache.

[Using offline files to allow caching of files for offline use](#)

Requirements and guidelines

BranchCache version support

You should be aware of which BranchCache versions ONTAP supports.

ONTAP supports BranchCache 1 and the enhanced BranchCache 2:

- When you configure BranchCache on the SMB server for the storage virtual machine (SVM), you can enable BranchCache 1, BranchCache 2, or all versions.

By default, all versions are enabled.

- If you enable only BranchCache 2, the remote office Windows client machines must support BranchCache 2.

Only SMB 3.0 or later clients support BranchCache 2.

For more information about BranchCache versions, see the Microsoft TechNet Library.

Related information

[Microsoft TechNet Library: technet.microsoft.com/en-us/library/](#)

Network protocol support requirements

You must be aware of the network protocol requirements for implementing ONTAP BranchCache.

You can implement the ONTAP BranchCache feature over IPv4 and IPv6 networks using SMB 2.1 or later.

All CIFS servers and branch office machines participating in the BranchCache implementation must have the SMB 2.1 or later protocol enabled. SMB 2.1 has protocol extensions that allow a client to participate in a BranchCache environment. This is the minimum SMB protocol version that offers BranchCache support. SMB

2.1 supports version BranchCache version 1.

If you want to use BranchCache version 2, SMB 3.0 is the minimum supported version. All CIFS servers and branch office machines participating in a BranchCache 2 implementation must have SMB 3.0 or later enabled.

If you have remote offices where some of the clients support only SMB 2.1 and some of the clients support SMB 3.0, you can implement a BranchCache configuration on the CIFS server that provides caching support over both BranchCache 1 and BranchCache 2.

Even though the Microsoft BranchCache feature supports using both the HTTP/HTTPS and SMB protocols as file access protocols, ONTAP BranchCache only supports the use of SMB.

ONTAP and Windows hosts version requirements

ONTAP and branch office Windows hosts must meet certain version requirements before you can configure BranchCache.

Before configuring BranchCache, you must ensure that the version of ONTAP on the cluster and participating branch office clients support SMB 2.1 or later and support the BranchCache feature. If you configure Hosted Cache mode, you must also ensure that you use a supported host for the cache server.

BranchCache 1 is supported on the following ONTAP versions and Windows hosts:

- Content server: storage virtual machine (SVM) with ONTAP
- Cache server: Windows Server 2008 R2 or Windows Server 2012 or later
- Peer or client: Windows 7 Enterprise, Windows 7 Ultimate, Windows 8, Windows Server 2008 R2 or Windows Server 2012 or later

BranchCache 2 is supported on the following ONTAP versions and Windows hosts:

- Content server: SVM with ONTAP
- Cache server: Windows Server 2012 or later
- Peer or client: Windows 8 or Windows Server 2012 or later

For the latest information about which Windows clients support BranchCache, see the Interoperability Matrix.

mysupport.netapp.com/matrix

Reasons ONTAP invalidates BranchCache hashes

Understanding the reasons why ONTAP invalidates hashes can be helpful as you plan your BranchCache configuration. It can help you decide which operating mode you should configure and can help you choose on which shares to enable BranchCache.

ONTAP must manage BranchCache hashes to ensure that hashes are valid. If a hash is not valid, ONTAP invalidates the hash and computes a new hash the next time that content is requested, assuming that BranchCache is still enabled.

ONTAP invalidates hashes for the following reasons:

- The server key is modified.

If the server key is modified, ONTAP invalidates all hashes in the hash store.

- A hash is flushed from the cache because the BranchCache hash store maximum size has been reached.

This is a tunable parameter and can be modified to meet your business requirements.

- A file is modified either through SMB or NFS access.
- A file for which there are computed hashes is restored using the `snap restore` command.
- A volume that contains SMB shares that are BranchCache-enabled is restored using the `snap restore` command.

Guidelines for choosing the hash store location

When configuring BranchCache, you choose where to store hashes and what size the hash store should be. Understanding the guidelines when choosing the hash store location and size can help you plan your BranchCache configuration on a CIFS-enabled SVM.

- You should locate the hash store on a volume where atime updates are permitted.

The access time on a hash file is used to keep frequently accessed files in the hash store. If atime updates are disabled, the creation time is used for this purpose. It is preferable to use atime to track frequently used files.

- You cannot store hashes on read-only file systems such as SnapMirror destinations and SnapLock volumes.
- If the maximum size of the hash store is reached, older hashes are flushed to make room for new hashes.

You can increase the maximum size of the hash store to reduce the amount of hashes that are flushed from the cache.

- If the volume on which you store hashes is unavailable or full, or if there is an issue with intra-cluster communication where the BranchCache service cannot retrieve hash information, BranchCache services are not available.

The volume might be unavailable because it is offline or because the storage administrator specified a new location for the hash store.

This does not cause issues with file access. If access to the hash store is impeded, ONTAP returns a Microsoft-defined error to the client, which causes the client to request the file using the normal SMB read request.

BranchCache recommendations

Before you configure BranchCache, there are certain recommendations you should keep in mind when deciding on which SMB shares you want to enable BranchCache caching.

You should keep the following recommendations in mind when deciding on which operating mode to use and on which SMB shares to enable BranchCache:

- The benefits of BranchCache are reduced when the data to be remotely cached changes frequently.
- BranchCache services are beneficial for shares containing file content that is reused by multiple remote office clients or by file content that is repeatedly accessed by a single remote user.
- Consider enabling caching for read-only content such as data in Snapshot copies and SnapMirror destinations.

Configure BranchCache

Configure BranchCache overview

You configure BranchCache on your SMB server using ONTAP commands. To implement BranchCache, you must also configure your clients, and optionally your hosted cache servers at the branch offices where you want to cache content.

If you configure BranchCache to enable caching on a share-by-share basis, you must enable BranchCache on the SMB shares for which you want to provide BranchCache caching services.

Requirements for configuring BranchCache

After meeting some prerequisites, you can set up BranchCache.

The following requirements must be met before configuring BranchCache on the CIFS server for your SVM:

- ONTAP must be installed on all nodes in the cluster.
- CIFS must be licensed and a CIFS server must be configured.
- IPv4 or IPv6 network connectivity must be configured.
- For BranchCache 1, SMB 2.1 or later must be enabled.
- For BranchCache 2, SMB 3.0 must be enabled and the remote Windows clients must support BranchCache 2.

Configure BranchCache on the SMB server

You can configure BranchCache to provide BranchCache services on a per-share basis. Alternatively, you can configure BranchCache to automatically enable caching on all SMB shares.

About this task

You can configure BranchCache on SVMs.

- You can create an all-shares BranchCache configuration if want to offer caching services for all content contained within all SMB shares on the CIFS server.
- You can create a per-share BranchCache configuration if you want to offer caching services for content contained within selected SMB shares on the CIFS server.

You must specify the following parameters when configuring BranchCache:

Required parameters	Description
<i>SVM name</i>	BranchCache is configured on a per SVM basis. You must specify on which CIFS-enabled SVM you want to configure the BranchCache service.
<i>Path to hash store</i>	<p>BranchCache hashes are stored in regular files on the SVM volume. You must specify the path to an existing directory where you want ONTAP to store the hash data. The BranchCache hash path must be read-writable. Read-only paths, such as Snapshot directories are not allowed. You can store hash data in a volume that contains other data or you can create a separate volume to store hash data.</p> <p>If the SVM is an SVM disaster recovery source, the hash path cannot be on the root volume. This is because the root volume is not replicated to the disaster recovery destination.</p> <p>The hash path can contain blanks and any valid file name characters.</p>

You can optionally specify the following parameters:

Optional parameters	Description
<i>Supported Versions</i>	ONTAP support BranchCache 1 and 2. You can enable version 1, version 2, or both versions. The default is to enable both versions.
<i>Maximum size of hash store</i>	<p>You can specify the size to use for the hash data store. If the hash data exceeds this value, ONTAP deletes older hashes to make room for newer hashes. The default size for the hash store is 1 GB.</p> <p>BranchCache performs more efficiently if hashes are not discarded in an overly aggressive manner. If you determine that hashes are discarded frequently because the hash store is full, you can increase the hash store size by modifying the BranchCache configuration.</p>

Optional parameters	Description
<i>Server key</i>	You can specify a server key that the BranchCache service uses to prevent clients from impersonating the BranchCache server. If you do not specify a server key, one is randomly generated when you create the BranchCache configuration. You can set the server key to a specific value so that if multiple servers are providing BranchCache data for the same files, clients can use hashes from any server using that same server key. If the server key contains any spaces, you must enclose the server key in quotation marks.
<i>Operating mode</i>	<p>The default is to enable BranchCache on a per-share basis.</p> <ul style="list-style-type: none"> • To create a BranchCache configuration where you enable BranchCache on a per-share basis, you can either not specify this optional parameter or you can specify <code>per-share</code>. • To automatically enable BranchCache on all shares, you must set the operating mode to <code>all-shares</code>.

Steps

1. Enable SMB 2.1 and 3.0 as needed:
 - a. Set the privilege level to advanced: `set -privilege advanced`
 - b. Check the configured SVM SMB settings to determine whether all needed versions of SMB are enabled: `vserver cifs options show -vserver vserver_name`
 - c. If necessary, enable SMB 2.1: `vserver cifs options modify -vserver vserver_name -smb2-enabled true`

The command enables both SMB 2.0 and SMB 2.1.

 - d. If necessary, enable SMB 3.0: `vserver cifs options modify -vserver vserver_name -smb3-enabled true`
 - e. Return to the admin privilege level: `set -privilege admin`
2. Configure BranchCache: `vserver cifs branchcache create -vserver vserver_name -hash -store-path path [-hash-store-max-size {integer[KB|MB|GB|TB|PB]}] [-versions {v1-enable|v2-enable|enable-all}] [-server-key text] -operating-mode {per-share|all-shares}`

The specified hash storage path must exist and must reside on a volume managed by the SVM. The path must also be located on a read-writable volume. The command fails if the path is read-only or does not exist.

If you want to use the same server key for additional SVM BranchCache configurations, record the value you enter for the server key. The server key does not appear when you display information about the BranchCache configuration.

3. Verify that the BranchCache configuration is correct: vserver cifs branchcache show -vserver *vserver_name*

Examples

The following commands verify that both SMB 2.1 and 3.0 are enabled and configure BranchCache to automatically enable caching on all SMB shares on SVM vs1:

```
cluster1::> set -privilege advanced
Warning: These advanced commands are potentially dangerous; use them
only when directed to do so by technical support personnel.
Do you wish to continue? (y or n): y

cluster1::*> vserver cifs options show -vserver vs1 -fields smb2-
enabled,smb3-enabled
vserver smb2-enabled smb3-enabled
-----
vs1      true          true

cluster1::*> set -privilege admin

cluster1::> vserver cifs branchcache create -vserver vs1 -hash-store-path
[hash_data] -hash-store-max-size 20GB -versions enable-all -server-key "my
server key" -operating-mode all-shares

cluster1::> vserver cifs branchcache show -vserver vs1

          Vserver: vs1
          Supported BranchCache Versions: enable_all
          Path to Hash Store: [hash_data]
          Maximum Size of the Hash Store: 20GB
          Encryption Key Used to Secure the Hashes: -
          CIFS BranchCache Operating Modes: all_shares
```

The following commands verify that both SMB 2.1 and 3.0 are enabled, configure BranchCache to enable caching on a per-share basis on SVM vs1, and verify the BranchCache configuration:

```

cluster1::> set -privilege advanced
Warning: These advanced commands are potentially dangerous; use them
only when directed to do so by technical support personnel.
Do you wish to continue? (y or n): y

cluster1::*> vserver cifs options show -vserver vs1 -fields smb2-
enabled,smb3-enabled
vserver smb2-enabled smb3-enabled
-----
vs1      true          true

cluster1::*> set -privilege admin

cluster1::> vserver cifs branchcache create -vserver vs1 -hash-store-path
[hash_data] -hash-store-max-size 20GB -versions enable-all -server-key "my
server key"

cluster1::> vserver cifs branchcache show -vserver vs1

                           Vserver: vs1
Supported BranchCache Versions: enable_all
                               Path to Hash Store: /hash_data
Maximum Size of the Hash Store: 20GB
Encryption Key Used to Secure the Hashes: -
CIFS BranchCache Operating Modes: per_share

```

Where to find information about configuring BranchCache at the remote office

After configuring BranchCache on the SMB server, you must install and configure BranchCache on client computers and, optionally, on caching servers at your remote office. Microsoft provides instructions for configuring BranchCache at the remote office.

Instructions for configuring branch office clients and, optionally, caching servers to use BranchCache are on

the Microsoft BranchCache web site.

[Microsoft BranchCache Docs: What's New](#)

Configure BranchCache-enabled SMB shares

Configure BranchCache-enabled SMB shares overview

After you configure BranchCache on the SMB server and at the branch office, you can enable BranchCache on SMB shares that contain content that you want to allow clients at branch offices to cache.

BranchCache caching can be enabled on all SMB shares on the SMB server or on a share-by-share basis.

- If you enable BranchCache on a share-by-share basis, you can enable BranchCache as you create the share or by modifying existing shares.

If you enable caching on an existing SMB share, ONTAP begins computing hashes and sending metadata to clients requesting content as soon as you enable BranchCache on that share.

- Any clients that have an existing SMB connection to a share do not get BranchCache support if BranchCache is subsequently enabled on that share.

ONTAP advertises BranchCache support for a share at the time the SMB session is set up. Clients that already have established sessions when BranchCache is enabled need to disconnect and reconnect to use cached content for this share.

If BranchCache on a SMB share is subsequently disabled, ONTAP stops sending metadata to the requesting client. A client that needs data retrieves it directly from the content server (SMB server).

Create a BranchCache-enabled SMB share

You can enable BranchCache on an SMB share when you create the share by setting the `branchcache` share property.

About this task

- If BranchCache is enabled on the SMB share, the share must have the offline files configuration set to manual caching.

This is the default setting when you create a share.

- You can also specify additional optional share parameters when you create the BranchCache-enabled share.
- You can set the `branchcache` property on a share even if BranchCache is not configured and enabled on the storage virtual machine (SVM).

However, if you want the share to offer cached content, you must configure and enable BranchCache on the SVM.

- Since there are no default share properties applied to the share when you use the `-share-properties` parameter, you must specify all other share properties that you want applied to the share in addition to the

branchcache share property by using a comma-delimited list.

- For more information, see the man page for the vserver cifs share create command.

Step

1. Create a BranchCache-enabled SMB share:

```
vserver cifs share create -vserver vserver_name -share-name share_name -path path -share-properties branchcache[,...]
```

2. Verify that the BranchCache share property is set on the SMB share by using the vserver cifs share show command.

Example

The following command creates a BranchCache-enabled SMB share named “data” with a path of /data on SVM vs1. By default, the offline files setting is set to manual:

```
cluster1::> vserver cifs share create -vserver vs1 -share-name data -path /data -share-properties branchcache,oplocks,browsable,changenotify

cluster1::> vserver cifs share show -vserver vs1 -share-name data
          Vserver: vs1
          Share: data
          CIFS Server NetBIOS Name: VS1
          Path: /data
          Share Properties: branchcache
                           oplocks
                           browsable
                           changenotify
          Symlink Properties: enable
          File Mode Creation Mask: -
          Directory Mode Creation Mask: -
          Share Comment: -
          Share ACL: Everyone / Full Control
          File Attribute Cache Lifetime: -
          Volume Name: data
          Offline Files: manual
          Vscan File-Operations Profile: standard
```

Related information

[Disabling BranchCache on a single SMB share](#)

Enable BranchCache on an existing SMB share

You can enable BranchCache on an existing SMB share by adding the branchcache share property to the existing list of share properties.

About this task

- If BranchCache is enabled on the SMB share, the share must have the offline files configuration set to

manual caching.

If the existing share's offline files setting is not set to manual caching, you must configure it by modifying the share.

- You can set the `branchcache` property on a share even if BranchCache is not configured and enabled on the storage virtual machine (SVM).

However, if you want the share to offer cached content, you must configure and enable BranchCache on the SVM.

- When you add the `branchcache` share property to the share, existing share settings and share properties are preserved.

The BranchCache share property is added to the existing list of share properties. For more information about using the `vserver cifs share properties add` command, see the man pages.

Steps

1. If necessary, configure the offline files share setting for manual caching:
 - a. Determine what the offline files share setting is by using the `vserver cifs share show` command.
 - b. If the offline files share setting is not set to manual, change it to the required value: `vserver cifs share modify -vserver vserver_name -share-name share_name -offline-files manual`
2. Enable BranchCache on an existing SMB share: `vserver cifs share properties add -vserver vserver_name -share-name share_name -share-properties branchcache`
3. Verify that the BranchCache share property is set on the SMB share: `vserver cifs share show -vserver vserver_name -share-name share_name`

Example

The following command enables BranchCache on an existing SMB share named "data2" with a path of /data2 on SVM vs1:

```

cluster1::> vserver cifs share show -vserver vs1 -share-name data2

          Vserver: vs1
          Share: data2
CIFS Server NetBIOS Name: VS1
          Path: /data2
Share Properties: oplocks
                  browsable
                  changenotify
                  showsnapshot
Symlink Properties: -
File Mode Creation Mask: -
Directory Mode Creation Mask: -
Share Comment: -
Share ACL: Everyone / Full Control
File Attribute Cache Lifetime: 10s
          Volume Name: -
Offline Files: manual
Vscan File-Operations Profile: standard

cluster1::> vserver cifs share properties add -vserver vs1 -share-name
data2 -share-properties branchcache

cluster1::> vserver cifs share show -vserver vs1 -share-name data2

          Vserver: vs1
          Share: data2
CIFS Server NetBIOS Name: VS1
          Path: /data2
Share Properties: oplocks
                  browsable
                  showsnapshot
                  changenotify
                  branchcache
Symlink Properties: -
File Mode Creation Mask: -
Directory Mode Creation Mask: -
Share Comment: -
Share ACL: Everyone / Full Control
File Attribute Cache Lifetime: 10s
          Volume Name: -
Offline Files: manual
Vscan File-Operations Profile: standard

```

[Manage and monitor the BranchCache configuration](#)

Modify BranchCache configurations

You can modify the configuration of the BranchCache service on SVMs, including changing the hash store directory path, the hash store maximum directory size, the operating mode, and which BranchCache versions are supported. You can also increase the size of the volume that contains the hash store.

Steps

1. Perform the appropriate action:

If you want to...	Enter the following...
Modify the hash store directory size	<pre>vserver cifs branchcache modify -vserver vserver_name -hash-store-max -size {integer[KB MB GB TB PB]}</pre>
Increase the size of the volume that contains the hash store	<pre>volume size -vserver vserver_name -volume volume_name -new-size new_size[k m g t]</pre> <p>If the volume containing the hash store fills up, you might be able to increase the size of the volume. You can specify the new volume size as a number followed by a unit designation.</p> <p>Learn more about managing FlexVol volumes</p>

If you want to...	Enter the following...
Modify the hash store directory path	<pre>vserver cifs branchcache modify -vserver vserver_name -hash-store-path path -flush-hashes {true false} If the SVM is an SVM disaster recovery source, the hash path cannot be on the root volume. This is because the root volume is not replicated to the disaster recovery destination.</pre> <p>The BranchCache hash path can contain blanks and any valid file name characters.</p> <p>If you modify the hash path, <code>-flush-hashes</code> is a required parameter that specifies whether you want ONTAP to flush the hashes from the original hash store location. You can set the following values for the <code>-flush-hashes</code> parameter:</p> <ul style="list-style-type: none"> • If you specify <code>true</code>, ONTAP deletes the hashes in the original location and creates new hashes in the new location as new requests are made by BranchCache-enabled clients. • If you specify <code>false</code>, the hashes are not flushed. <p>In this case, you can choose to reuse the existing hashes later by changing the hash store path back to the original location.</p>
Change the operating mode	<pre>vserver cifs branchcache modify -vserver vserver_name -operating-mode {per-share all-shares disable}</pre> <p>You should be aware of the following when modifying the operating mode:</p> <ul style="list-style-type: none"> • ONTAP advertises BranchCache support for a share when the SMB session is set up. • Clients that already have established sessions when BranchCache is enabled need to disconnect and reconnect to use cached content for this share.
Change the BranchCache version support	<pre>vserver cifs branchcache modify -vserver vserver_name -versions {v1- enable v2-enable enable-all}</pre>

2. Verify the configuration changes by using the `vserver cifs branchcache show` command.

Display information about BranchCache configurations

You can display information about BranchCache configurations on storage virtual machines (SVMs), which can be used when verifying a configuration or when determining current settings before modifying a configuration.

Step

1. Perform one of the following actions:

If you want to display...	Enter this command...
Summary information about BranchCache configurations on all SVMs	vserver cifs branchcache show
Detailed information about the configuration on a specific SVM	vserver cifs branchcache show -vserver <i>vserver_name</i>

Example

The following example displays information about the BranchCache configuration on SVM vs1:

```
cluster1::> vserver cifs branchcache show -vserver vs1

          Vserver: vs1
          Supported BranchCache Versions: enable_all
          Path to Hash Store: /hash_data
          Maximum Size of the Hash Store: 20GB
          Encryption Key Used to Secure the Hashes: -
          CIFS BranchCache Operating Modes: per_share
```

Change the BranchCache server key

You can change the BranchCache server key by modifying the BranchCache configuration on the storage virtual machine (SVM) and specifying a different server key.

About this task

You can set the server key to a specific value so that if multiple servers are providing BranchCache data for the same files, clients can use hashes from any server using that same server key.

When you change the server key, you must also flush the hash cache. After flushing the hashes, ONTAP creates new hashes as new requests are made by BranchCache-enabled clients.

Steps

1. Change the server key by using the following command: `vserver cifs branchcache modify -vserver vserver_name -server-key text -flush-hashes true`

When configuring a new server key, you must also specify `-flush-hashes` and set the value to `true`.

- Verify that the BranchCache configuration is correct by using the `vserver cifs branchcache show` command.

Example

The following example sets a new server key that contains spaces and flushes the hash cache on SVM vs1:

```
cluster1::> vserver cifs branchcache modify -vserver vs1 -server-key "new  
vserver secret" -flush-hashes true  
  
cluster1::> vserver cifs branchcache show -vserver vs1  
  
          Vserver: vs1  
Supported BranchCache Versions: enable_all  
Path to Hash Store: /hash_data  
Maximum Size of the Hash Store: 20GB  
Encryption Key Used to Secure the Hashes: -  
CIFS BranchCache Operating Modes: per_share
```

[Reasons ONTAP invalidates BranchCache hashes](#)

Pre-compute BranchCache hashes on specified paths

You can configure the BranchCache service to pre-compute hashes for a single file, for a directory, or for all files in a directory structure. This can be helpful if you want to compute hashes on data in a BranchCache-enabled share during off, non-peak hours.

About this task

If you want to collect a data sample before you display hash statistics, you must use the `statistics start` and optional `statistics stop` commands.

- You must specify the storage virtual machine (SVM) and path on which you want to pre-compute hashes.
- You must also specify whether you want hashes computed recursively.
- If you want hashes computed recursively, the BranchCache service traverses the entire directory tree under the specified path, and computes hashes for each eligible object.

Steps

- Pre-compute hashes as desired:

If you want to pre-compute hashes on...	Enter the command...
A single file or directory	<code>vserver cifs branchcache hash-create -vserver vserver_name -path path -recurse false</code>

If you want to pre-compute hashes on...	Enter the command...
Recursively on all files in a directory structure	vserver cifs branchcache hash-create -vserver vserver_name -path absolute_path -recurse true

2. Verify that hashes are being computed by using the `statistics` command:
- Display statistics for the `hashd` object on the desired SVM instance: `statistics show -object hashd -instance vserver_name`
 - Verify that the number of hashes created is increasing by repeating the command.

Examples

The following example creates hashes on the path `/data` and on all contained files and subdirectories on SVM `vs1`:

```

cluster1::> vserver cifs branchcache hash-create -vserver vs1 -path /data
-recurse true

cluster1::> statistics show -object hashd -instance vs1
Object: hashd
Instance: vs1
Start-time: 9/6/2012 19:09:54
End-time: 9/6/2012 19:11:15
Cluster: cluster1

| Counter                         | Value                                |
|---------------------------------|--------------------------------------|
| branchcache_hash_created        | 85                                   |
| branchcache_hash_files_replaced | 0                                    |
| branchcache_hash_rejected       | 0                                    |

[Performance monitoring setup](#)

Flush hashes from the SVM BranchCache hash store

You can flush all cached hashes from the BranchCache hash store on the storage virtual machine (SVM). This can be useful if you have changed the branch office BranchCache configuration. For example, if you recently reconfigured the caching mode from distributed caching to hosted caching mode, you would want to flush the hash store.

About this task

After flushing the hashes, ONTAP creates new hashes as new requests are made by BranchCache-enabled clients.

Step

1. Flush the hashes from the BranchCache hash store: `vserver cifs branchcache hash-flush -vserver vserver_name`

`vserver cifs branchcache hash-flush -vserver vs1`

Display BranchCache statistics

You can display BranchCache statistics to, among other things, identify how well caching is performing, determine whether your configuration is providing cached content to clients, and determine whether hash files were deleted to make room for more recent hash data.

About this task

The `hashd` statistic object contains counters that provide statistical information about BranchCache hashes. The `cifs` statistic object contains counters that provide statistical information about BranchCache-related activity. You can collect and display information about these objects at the advanced-privilege level.

Steps

1. Set the privilege level to advanced: `set -privilege advanced`

```
cluster1::> set -privilege advanced

Warning: These advanced commands are potentially dangerous; use them
only when directed to do so by support personnel.

Do you want to continue? {y|n}: y
```

2. Display the BranchCache-related counters by using the `statistics catalog counter show` command.

For more information about statistics counters, see the man page for this command.

```
cluster1::*> statistics catalog counter show -object hashd

Object: hashd
      Counter          Description
```

```

-----
branchcache_hash_created      Number of times a request to generate
                               BranchCache hash for a file succeeded.

branchcache_hash_files_replaced
                               Number of times a BranchCache hash file
was
                               deleted to make room for more recent
hash
                               data. This happens if the hash store
size is
                               exceeded.

branchcache_hash_rejected    Number of times a request to generate
                               BranchCache hash data failed.

branchcache_hash_store_bytes
                               Total number of bytes used to store hash
data.

branchcache_hash_store_size Total space used to store BranchCache
hash
                               data for the Vserver.

instance_name                Instance Name
instance_uuid                Instance UUID
node_name                    System node name
node_uuid                    System node id

9 entries were displayed.

```

```
cluster1::>*> statistics catalog counter show -object cifs
```

```
Object: cifs
```

Counter	Description
active_searches	Number of active searches over SMB and SMB2
auth_reject_too_many	Authentication refused after too many requests were made in rapid succession
avg_directory_depth	Average number of directories crossed by SMB
avg_junction_depth	Average number of junctions crossed by SMB
branchcache_hash_fetch_fail	Total number of times a request to fetch hash data failed. These are failures when attempting to read existing hash data.

It does not include attempts to fetch hash data that has not yet been generated.

branchcache_hash_fetch_ok Total number of times a request to fetch hash data succeeded.

branchcache_hash_sent_bytes Total number of bytes sent to clients requesting hashes.

branchcache_missing_hash_bytes Total number of bytes of data that had to be read by the client because the hash for that content was not available on the server.

....Output truncated....

3. Collect BranchCache-related statistics by using the `statistics start` and `statistics stop` commands.

```
cluster1::>*> statistics start -object cifs -vserver vs1 -sample-id 11
Statistics collection is being started for Sample-id: 11

cluster1::>*> statistics stop -sample-id 11
Statistics collection is being stopped for Sample-id: 11
```

4. Display the collected BranchCache statistics by using the `statistics show` command.

```
cluster1::>* statistics show -object cifs -counter  
branchcache_hash_sent_bytes -sample-id 11
```

Object: cifs
Instance: vs1
Start-time: 12/26/2012 19:50:24
End-time: 12/26/2012 19:51:01
Cluster: cluster1

Counter	Value
branchcache_hash_sent_bytes	0

```
cluster1::>* statistics show -object cifs -counter  
branchcache_missing_hash_bytes -sample-id 11
```

Object: cifs
Instance: vs1
Start-time: 12/26/2012 19:50:24
End-time: 12/26/2012 19:51:01
Cluster: cluster1

Counter	Value
branchcache_missing_hash_bytes	0

5. Return to the admin privilege level: set -privilege admin

```
cluster1::>* set -privilege admin
```

Support for BranchCache Group Policy Objects

ONTAP BranchCache provides support for BranchCache Group Policy Objects (GPOs),

which allow centralized management for certain BranchCache configuration parameters. There are two GPOs used for BranchCache, the Hash Publication for BranchCache GPO and the Hash Version Support for BranchCache GPO.

- **Hash Publication for BranchCache GPO**

The Hash Publication for BranchCache GPO corresponds to the `-operating-mode` parameter. When GPO updates occur, this value is applied to storage virtual machine (SVM) objects contained within the organizational unit (OU) to which the group policy applies.

- **Hash Version Support for BranchCache GPO**

The Hash Version Support for BranchCache GPO corresponds to the `-versions` parameter. When GPO updates occur, this value is applied to SVM objects contained within the organizational unit to which the group policy applies.

Related information

[Applying Group Policy Objects to CIFS servers](#)

Display information about BranchCache Group Policy Objects

You can display information about the CIFS server's Group Policy Object (GPO) configuration to determine whether BranchCache GPOs are defined for the domain to which the CIFS server belongs and, if so, what the allowed settings are. You can also determine whether BranchCache GPO settings are applied to the CIFS server.

About this task

Even though a GPO setting is defined within the domain to which the CIFS server belongs, it is not necessarily applied to the organizational unit (OU) containing the CIFS-enabled storage virtual machine (SVM). Applied GPO setting are the subset of all defined GPOs that are applied to the CIFS-enabled SVM. BranchCache settings applied through GPOs override settings applied through the CLI.

Steps

1. Display the defined BranchCache GPO setting for the Active Directory domain by using the `vserver cifs group-policy show-defined` command.

This example does not display all of the available output fields for the command. Output is truncated.

```
cluster1::> vserver cifs group-policy show-defined -vserver vs1

Vserver: vs1
-----
    GPO Name: Default Domain Policy
    Level: Domain
    Status: enabled
Advanced Audit Settings:
    Object Access:
        Central Access Policy Staging: failure
Registry Settings:
    Refresh Time Interval: 22
    Refresh Random Offset: 8
    Hash Publication Mode for BranchCache: per-share
    Hash Version Support for BranchCache: version1
[...]

    GPO Name: Resultant Set of Policy
    Status: enabled

[Enabling or disabling GPO support on a CIFS server](#)

[Disable BranchCache on SMB shares](#)

[Disable BranchCache on SMB shares overview](#)

If you do not want to provide BranchCache caching services on certain SMB shares but you might want to provide caching services on those shares later, you can disable BranchCache on a share-by-share basis. If you have BranchCache configured to offer caching on all shares but you want to temporarily disable all caching services, you can modify the BranchCache configuration to stop automatic caching on all shares.

If BranchCache on an SMB share is subsequently disabled after first being enabled, ONTAP stops sending metadata to the requesting client. A client that needs data retrieves it directly from the content server (CIFS server on the storage virtual machine (SVM)).

Related information

[Configuring BranchCache-enabled SMB shares](#)

Disable BranchCache on a single SMB share

If you do not want to offer caching services on certain shares that previously offered cached content, you can disable BranchCache on an existing SMB share.

Step

1. Enter the following command:
`vserver cifs share properties remove -vserver
vserver_name -share-name share_name -share-properties branchcache`

The BranchCache share property is removed. Other applied share properties remain in effect.

Example

The following command disables BranchCache on an existing SMB share named “data2”:

```
cluster1::> vserver cifs share show -vserver vs1 -share-name data2
```

```
          Vserver: vs1
          Share: data2
CIFS Server NetBIOS Name: VS1
          Path: /data2
Share Properties: oplocks
                  browsable
                  changenotify
                  attributecache
                  branchcache
Symlink Properties: -
File Mode Creation Mask: -
Directory Mode Creation Mask: -
Share Comment: -
          Share ACL: Everyone / Full Control
File Attribute Cache Lifetime: 10s
          Volume Name: -
          Offline Files: manual
Vscan File-Operations Profile: standard
```

```
cluster1::> vserver cifs share properties remove -vserver vs1 -share-name
data2 -share-properties branchcache
```

```
cluster1::> vserver cifs share show -vserver vs1 -share-name data2
```

```
          Vserver: vs1
          Share: data2
CIFS Server NetBIOS Name: VS1
          Path: /data2
Share Properties: oplocks
                  browsable
                  changenotify
                  attributecache
Symlink Properties: -
File Mode Creation Mask: -
Directory Mode Creation Mask: -
Share Comment: -
          Share ACL: Everyone / Full Control
File Attribute Cache Lifetime: 10s
          Volume Name: -
          Offline Files: manual
Vscan File-Operations Profile: standard
```

Stop automatic caching on all SMB shares

If your BranchCache configuration automatically enables caching on all SMB shares on each storage virtual machine (SVM), you can modify the BranchCache configuration to stop automatically caching content for all SMB shares.

About this task

To stop automatic caching on all SMB shares, you change the BranchCache operating mode to per-share caching.

Steps

1. Configure BranchCache to stop automatic caching on all SMB shares: `vserver cifs branchcache modify -vserver vserver_name -operating-mode per-share`
2. Verify that the BranchCache configuration is correct: `vserver cifs branchcache show -vserver vserver_name`

Example

The following command changes the BranchCache configuration on storage virtual machine (SVM, formerly known as Vserver) vs1 to stop automatic caching on all SMB shares:

```
cluster1::> vserver cifs branchcache modify -vserver vs1 -operating-mode  
per-share  
  
cluster1::> vserver cifs branchcache show -vserver vs1  
  
          Vserver: vs1  
Supported BranchCache Versions: enable_all  
          Path to Hash Store: /hash_data  
Maximum Size of the Hash Store: 20GB  
Encryption Key Used to Secure the Hashes: -  
CIFS BranchCache Operating Modes: per_share
```

Disable or enable BranchCache on the SVM

What happens when you disable or reenable BranchCache on the CIFS server

If you previously configured BranchCache but do not want the branch office clients to use cached content, you can disable caching on the CIFS server. You must be aware of what happens when you disable BranchCache.

When you disable BranchCache, ONTAP no longer computes hashes or sends the metadata to the requesting client. However, there is no interruption to file access. Thereafter, when BranchCache-enabled clients request metadata information for content they want to access, ONTAP responds with a Microsoft-defined error, which causes the client to send a second request, requesting the actual content. In response to the request for content, the CIFS server sends the actual content that is stored on the storage virtual machine (SVM).

After BranchCache is disabled on the CIFS server, SMB shares do not advertise BranchCache capabilities. To access data on new SMB connections, clients make normal read SMB requests.

You can reenable BranchCache on the CIFS server at any time.

- Because the hash store is not deleted when you disable BranchCache, ONTAP can use the stored hashes when replying to hash requests after you reenable BranchCache, provided that the requested hash is still valid.
- Any clients that have made SMB connections to BranchCache-enabled shares during the time when BranchCache was disabled do not get BranchCache support if BranchCache is subsequently reenabled.

This is because ONTAP advertises BranchCache support for a share at the time the SMB session is set up. Clients that established sessions to BranchCache-enabled shares while BranchCache was disabled need to disconnect and reconnect to use cached content for this share.

 If you do not want to save the hash store after you disable BranchCache on a CIFS server, you can manually delete it. If you reenable BranchCache, you must ensure that the hash store directory exists. After BranchCache is reenabled, BranchCache-enabled shares advertise BranchCache capabilities. ONTAP creates new hashes as new requests are made by BranchCache-enabled clients.

Disable or enable BranchCache

You can disable BranchCache on the storage virtual machine (SVM) by changing the BranchCache operating mode to `disabled`. You can enable BranchCache at any time by changing the operating mode to either offer BranchCache services per-share or automatically for all shares.

Steps

1. Run the appropriate command:

If you want to...	Then enter the following...
Disable BranchCache	<code>vserver cifs branchcache modify -vserver vserver_name -operating-mode disable</code>
Enable BranchCache per share	<code>vserver cifs branchcache modify -vserver vserver_name -operating-mode per-share</code>
Enable BranchCache for all shares	<code>vserver cifs branchcache modify -vserver vserver_name -operating-mode all-shares</code>

2. Verify that the BranchCache operating mode is configured with the desired setting: `vserver cifs branchcache show -vserver vserver_name`

Example

The following example disables BranchCache on SVM vs1:

```

cluster1::> vserver cifs branchcache modify -vserver vs1 -operating-mode
disable

cluster1::> vserver cifs branchcache show -vserver vs1

          Vserver: vs1
Supported BranchCache Versions: enable_all
          Path to Hash Store: /hash_data
Maximum Size of the Hash Store: 20GB
Encryption Key Used to Secure the Hashes: -
          CIFS BranchCache Operating Modes: disable

```

Delete the BranchCache configuration on SVMs

What happens when you delete the BranchCache configuration

If you previously configured BranchCache but do not want the storage virtual machine (SVM) to continue providing cached content, you can delete the BranchCache configuration on the CIFS server. You must be aware of what happens when you delete the configuration.

When you delete the configuration, ONTAP removes the configuration information for that SVM from the cluster and stops the BranchCache service. You can choose whether ONTAP should delete the hash store on the SVM.

Deleting the BranchCache configuration does not disrupt access by BranchCache-enabled clients. Thereafter, when BranchCache-enabled clients request metadata information on existing SMB connections for content that is already cached, ONTAP responds with a Microsoft defined error, which causes the client to send a second request, requesting the actual content. In response to the request for content, the CIFS server sends the actual content that is stored on the SVM.

After the BranchCache configuration is deleted, SMB shares do not advertise BranchCache capabilities. To access content that has not previously been cached using new SMB connections, clients make normal read SMB requests.

Delete the BranchCache configuration

The command you use for deleting the BranchCache service on your storage virtual machine (SVM) differs depending on whether you want to delete or keep existing hashes.

Step

1. Run the appropriate command:

If you want to...	Then enter the following...
Delete the BranchCache configuration and delete existing hashes	vserver cifs branchcache delete -vserver vserver_name -flush-hashes true

If you want to...	Then enter the following...
Delete the BranchCache configuration but keep existing hashes	vserver cifs branchcache delete -vserver <i>vserver_name</i> -flush-hashes false

Example

The following example deletes the BranchCache configuration on SVM vs1 and deletes all existing hashes:

```
cluster1::> vserver cifs branchcache delete -vserver vs1 -flush-hashes  
true
```

What happens to BranchCache when reverting

It is important to understand what happens when you revert ONTAP to a release that does not support BranchCache.

- When you revert to a version of ONTAP that does not support BranchCache, the SMB shares do not advertise BranchCache capabilities to BranchCache-enabled clients; therefore, the clients do not request hash information.

Instead, they request the actual content using normal SMB read requests. In response to the request for content, the SMB server sends the actual content that is stored on the storage virtual machine (SVM).

- When a node hosting a hash store is reverted to a release that does not support BranchCache, the storage administrator needs to manually revert the BranchCache configuration using a command that is printed out during the revert.

This command deletes the BranchCache configuration and hashes.

After the revert completes, the storage administrator can manually delete the directory that contained the hash store if desired.

Improve Microsoft remote copy performance

Improve Microsoft remote copy performance overview

Microsoft Offloaded Data Transfer (ODX), also known as *copy offload*, enables direct data transfers within or between compatible storage devices without transferring the data through the host computer.

ONTAP supports ODX for both the SMB and SAN protocols. The source can be either a CIFS server or LUN, and the destination can be either a CIFS server or LUN.

In non-ODX file transfers, the data is read from the source and is transferred across the network to the client computer. The client computer transfers the data back over the network to the destination. In summary, the

client computer reads the data from the source and writes it to the destination. With ODX file transfers, data is copied directly from the source to the destination.

Because ODX offloaded copies are performed directly between the source and destination storage, there are significant performance benefits. The performance benefits realized include faster copy time between source and destination, reduced resource utilization (CPU, memory) on the client, and reduced network I/O bandwidth utilization.

For SMB environments, this functionality is only available when both the client and the storage server support SMB 3.0 and the ODX feature. For SAN environments, this functionality is only available when both the client and the storage server support the ODX feature. Client computers that support ODX and have ODX enabled automatically and transparently use offloaded file transfer when moving or copying files. ODX is used irrespective of whether you drag-and-drop files through Windows Explorer or use command-line file copy commands, or whether a client application initiates file copy requests.

Related information

[Improving client response time by providing SMB automatic node referrals with Auto Location](#)

[SMB configuration for Microsoft Hyper-V and SQL Server](#)

How ODX works

ODX copy offload uses a token-based mechanism for reading and writing data within or between ODX-enabled CIFS servers. Instead of routing the data through the host, the CIFS server sends a small token, which represents the data, to the client. The ODX client presents that token to the destination server, which then can transfer the data represented by that token from the source to the destination.

When an ODX client learns that the CIFS server is ODX-capable, it opens the source file and requests a token from the CIFS server. After opening the destination file, the client uses the token to instruct the server to copy the data directly from the source to the destination.

The source and destination can be on the same storage virtual machine (SVM) or on different SVMs, depending on the scope of the copy operation.

The token serves as a point-in-time representation of the data. As an example, when you copy data between storage locations, a token representing a data segment is returned to the requesting client, which the client copies to the destination, thereby removing the need to copy the underlying data through the client.

ONTAP supports tokens that represent 8 MB of data. ODX copies of greater than 8 MB are performed by using multiple tokens, with each token representing 8 MB of data.

The following figure explains the steps that are involved with an ODX copy operation:

1. A user copies or moves a file by using Windows Explorer, a command-line interface, or as part of a virtual machine migration, or an application initiates file copies or moves.
2. The ODX-capable client automatically translates this transfer request into an ODX request.

The ODX request that is sent to the CIFS server contains a request for a token.

3. If ODX is enabled on the CIFS server and the connection is over SMB 3.0, the CIFS server generates a token, which is a logical representation of the data on the source.
4. The client receives a token that represents the data and sends it with the write request to the destination CIFS server.

This is the only data that is copied over the network from the source to the client and then from the client to the destination.

5. The token is delivered to the storage subsystem.
6. The SVM internally performs the copy or move.

If the file that is copied or moved is larger than 8 MB, multiple tokens are needed to perform the copy. Steps 2 through 6 as performed as needed to complete the copy.

If there is a failure with the ODX offloaded copy, the copy or move operation falls back to traditional reads and writes for the copy or move operation. Similarly, if the destination CIFS server does not support ODX or ODX is disabled, the copy or move operation falls back to traditional reads and writes for the copy or move operation.

Requirements for using ODX

Before you can use ODX for copy offloads with your storage virtual machine (SVM), you need to be aware of certain requirements.

ONTAP version requirements

ONTAP releases support ODX for copy offloads.

SMB version requirements

- ONTAP supports ODX with SMB 3.0 and later.
- SMB 3.0 must be enabled on the CIFS server before ODX can be enabled:
 - Enabling ODX also enables SMB 3.0, if it is not already enabled.
 - Disabling SMB 3.0 also disables ODX.

Windows server and client requirements

Before you can use ODX for copy offloads, the Windows client must support the feature. Support for ODX starts with Windows 2012 Server and Windows 8.

The Interoperability Matrix contains the latest information about supported Windows clients.

[NetApp Interoperability Matrix Tool](#)

Volume requirements

- Source volumes must be a minimum of 1.25 GB.
- Deduplication must be enabled on volumes used with copy offload.
- If you use compressed volumes, the compression type must be adaptive and only compression group size 8K is supported.

Secondary compression type is not supported.

Guidelines for using ODX

Before you can use ODX for copy offload, you need to be aware of the guidelines. For example, you need to know on which types of volumes you can use ODX and you need to understand the intra-cluster and inter-cluster ODX considerations.

Volume guidelines

- You cannot use ODX for copy offload with the following volume configurations:
 - Source volume size is less than 1.25 GB

The volume size must be 1.25 GB or larger to use ODX.

- Read-only volumes

ODX is not used for files and folders residing in load-sharing mirrors or in SnapMirror or SnapVault destination volumes.

- If the source volume is not deduplicated
- ODX copies are supported only for intra-cluster copies.

You cannot use ODX to copy files or folders to a volume in another cluster.

Other guidelines

- In SMB environments, to use ODX for copy offload, the files must be 256 kb or larger.

Smaller files are transferred using a traditional copy operation.

- ODX copy offload uses deduplication as part of the copy process.

If you do not want deduplication to occur on SVM volumes when copying or moving data, you should disable ODX copy offload on that SVM.

- The application that performs the data transfer must be written to support ODX.

Application operations that support ODX include the following:

- Hyper-V management operations, such as creating and converting virtual hard disks (VHDs), managing Snapshot copies, and copying files between virtual machines
- Windows Explorer operations
- Windows PowerShell copy commands
- Windows command prompt copy commands

Robocopy at the Windows command prompt supports ODX.

The applications must be running on Windows servers or clients that support ODX.

For more information about supported ODX applications on Windows servers and clients, consult the Microsoft TechNet Library.

Related information

[Microsoft TechNet Library: technet.microsoft.com/en-us/library/](http://technet.microsoft.com/en-us/library/)

Use cases for ODX

You should be aware of the use cases for using ODX on SVMs so that you can determine under what circumstances ODX provides you with performance benefits.

Windows servers and clients that support ODX use copy offload as the default way of copying data across remote servers. If the Windows server or client does not support ODX or the ODX copy offload fails at any point, the copy or move operation falls back to traditional reads and writes for the copy or move operation.

The following use cases support using ODX copies and moves:

- Intra-volume

The source and destination files or LUNs are within the same volume.

- Inter-volume, same node, same SVM

The source and destination files or LUNs are on different volumes that are located on the same node. The data is owned by the same SVM.

- Inter-volume, different nodes, same SVM

The source and destination files or LUNs are on different volumes that are located on different nodes. The data is owned by the same SVM.

- Inter-SVM, same node

The source and destination file or LUNs are on different volumes that are located on the same node. The data is owned by different SVMs.

- Inter-SVM, different nodes

The source and destination file or LUNs are on different volumes that are located on different nodes. The data is owned by different SVMs.

- Inter-cluster

The source and destination LUNs are on different volumes that are located on different nodes across clusters. This is only supported for SAN and does not work for CIFS.

There are some additional special use cases:

- With the ONTAP ODX implementation, you can use ODX to copy files between SMB shares and FC or iSCSI attached virtual drives.

You can use Windows Explorer, the Windows CLI or PowerShell, Hyper-V, or other applications that support ODX to copy or move files seamlessly using ODX copy offload between SMB shares and connected LUNs, provided that the SMB shares and LUNs are on the same cluster.

- Hyper-V provides some additional use cases for ODX copy offload:

- You can use ODX copy offload pass-through with Hyper-V to copy data within or across virtual hard disk (VHD) files or to copy data between mapped SMB shares and connected iSCSI LUNs within the same cluster.

This allows copies from guest operating systems to pass through to the underlying storage.

- When creating fixed-sized VHDs, ODX is used for initializing the disk with zeros, using a well-known zeroed token.
 - ODX copy offload is used for virtual machine storage migration if the source and destination storage is on the same cluster.

To take advantage of the use cases for ODX copy offload pass-through with Hyper-V, the guest operating system must support ODX and the guest operating system's disks must be SCSI disks backed by storage (either SMB or SAN) that supports ODX. IDE disks on the guest operating system do not support ODX pass-through.

Enable or disable ODX

You can enable or disable ODX on storage virtual machines (SVMs). The default is to enable support for ODX copy offload if SMB 3.0 is also enabled.

Before you begin

SMB 3.0 must be enabled.

About this task

If you disable SMB 3.0, ONTAP also disables SMB ODX. If you reenable SMB 3.0, you must manually reenable SMB ODX.

Steps

1. Set the privilege level to advanced: `set -privilege advanced`
2. Perform one of the following actions:

If you want ODX copy offload to be...	Enter the command...
Enabled	<code>vserver cifs options modify -vserver vserver_name -copy-offload-enabled true</code>
Disabled	<code>vserver cifs options modify -vserver vserver_name -copy-offload-enabled false</code>

3. Return to the admin privilege level: `set -privilege admin`

Example

The following example enables ODX copy offload on SVM vs1:

```
cluster1::> set -privilege advanced
Warning: These advanced commands are potentially dangerous; use them
only when directed to do so by technical support personnel.
Do you wish to continue? (y or n): y

cluster1::*> vserver cifs options modify -vserver vs1 -copy-offload
-enabled true

cluster1::*> set -privilege admin
```

Available SMB server options

Improve client response time by providing SMB automatic node referrals with Auto Location

Improve client response time by providing SMB automatic node referrals with Auto Location overview

Auto Location uses SMB automatic node referrals to increase SMB client performance on storage virtual machines (SVMs). Automatic node referrals automatically redirect the requesting client to a LIF on the node SVM that is hosting the volume in which the data resides, which can lead to improved client response times.

When an SMB client connects to an SMB share hosted on the SVM, it might connect using a LIF that is on a node that does not own the requested data. The node to which the client is connected accesses data owned by another node by using the cluster network. The client can experience faster response times if the SMB connection uses a LIF located on the node containing the requested data:

- ONTAP provides this functionality by using Microsoft DFS referrals to inform SMB clients that a requested file or folder in the namespace is hosted somewhere else.

A node makes a referral when it determines that there is an SVM LIF on the node containing the data.

- Automatic node referrals are supported for IPv4 and IPv6 LIF IP addresses.
- Referrals are made based on the location of the root of the share through which the client is connected.
- The referral occurs during SMB negotiation.

The referral is made before the connection is established. After ONTAP refers the SMB client to the target node, the connection is made, and the client accesses data through the referred LIF path from that point on. This allows the clients faster access to the data and avoids extra cluster communication.

If a share spans multiple junction points and some of the junctions are to volumes contained on other nodes, data within the share is spread across multiple nodes. Because ONTAP provides referrals that are local to the root of the share, ONTAP must use the cluster network to retrieve the data contained within these non-local volumes. With this type of namespace architecture, automatic node referrals might not provide significant performance benefits.

If the node hosting the data does not have an available LIF, ONTAP establishes the connection using the LIF chosen by the client. After a file is opened by an SMB client, it continues to access the file through the same referred connection.

If, for any reason, the CIFS server cannot make a referral, there is no disruption to SMB service. The SMB connection is established as if automatic node referrals were not enabled.

Requirements and guidelines for using automatic node referrals

Before you can use SMB automatic node referrals, also known as *autolocation*, you need to be aware of certain requirements, including which versions of ONTAP support the feature. You also need to know about supported SMB protocol versions and certain other

special guidelines.

ONTAP version and license requirements

- All nodes in the cluster must be running a version of ONTAP that supports automatic node referrals.
- Widelinks must be enabled on a SMB share to use autolocation.
- CIFS must be licensed, and an SMB server must exist on the SVMs.

SMB protocol version requirements

- For SVMs, ONTAP supports automatic node referrals on all versions of SMB.

SMB client requirements

All Microsoft clients supported by ONTAP support SMB automatic node referrals.

The Interoperability Matrix contains the latest information about which Windows clients ONTAP supports.

[NetApp Interoperability Matrix Tool](#)

Data LIF requirements

If you want to use a data LIF as a potential referral for SMB clients, you must create data LIFs with both NFS and CIFS enabled.

Automatic node referrals can fail to work if the target node contains data LIFs that are enabled only for the NFS protocol, or enabled only for the SMB protocol.

If this requirement is not met, data access is not affected. The SMB client maps the share using the original LIF that the client used to connect to the SVM.

NTLM authentication requirements when making a referred SMB connection

NTLM authentication must be allowed on the domain containing the CIFS server and on the domains containing clients that want to use automatic node referrals.

When making a referral, the SMB server refers an IP address to the Windows client. Because NTLM authentication is used when making a connection using an IP address, Kerberos authentication is not performed for referred connections.

This happens because the Windows client cannot craft the service principal name used by Kerberos (which is of the form `service/NetBIOS_name` and `service/FQDN`), which means that the client cannot request a Kerberos ticket to the service.

Guidelines for using automatic node referrals with the home directory feature

When shares are configured with the home directory share property enabled, there can be one or more home directory search paths configured for a home directory configuration. The search paths can point to volumes contained on each node containing SVM volumes. Clients receive a referral and, if an active, local data LIF is available, connect through a referred LIF that is local to the home user's home directory.

There are guidelines when SMB 1.0 clients access dynamic home directories with automatic node referrals enabled. This is because SMB 1.0 clients require the automatic node referral before they have authenticated, which is before the SMB server has the user's name. However, SMB home directory access works correctly for

SMB 1.0 clients if the following statements are true:

- SMB home directories are configured to use simple names, such as "%w" (Windows user name) or "%u" (mapped UNIX user name), and not domain-name style names, such as "%d\%w" (domain-name\user-name).
- When creating home directory shares, the CIFS home directory shares names are configured with variables ("%w" or "%u"), and not with static names, such as "HOME".

For SMB 2.x and SMB 3.0 clients, there are no special guidelines when accessing home directories using automatic node referrals.

Guidelines for disabling automatic node referrals on CIFS servers with existing referred connections

If you disable automatic node referrals after the option has been enabled, clients currently connected to a referred LIF keep the referred connection. Because ONTAP uses DFS referrals as the mechanism for SMB automatic node referrals, clients can even reconnect to the referred LIF after you disable the option until the client's cached DFS referral for the referred connection times out. This is true even in the case of a revert to a version of ONTAP that does not support automatic node referrals. Clients continue to use referrals until the DFS referral times out from the client's cache.

Autolocation uses SMB automatic node referrals to increase SMB client performance by referring clients to the LIF on the node that owns the data volume of an SVM. When an SMB client connects to an SMB share hosted on an SVM, it might connect using a LIF on a node that does not own the requested data and uses cluster interconnect network to retrieve data. The client can experience faster response times if the SMB connection uses a LIF located on the node containing the requested data.

ONTAP provides this functionality by using Microsoft Distributed File System (DFS) referrals to inform SMB clients that a requested file or folder in the namespace is hosted somewhere else. A node makes a referral when it determines that there is an SVM LIF on the node containing the data. Referrals are made based on the location of the root of the share through which the client is connected.

The referral occurs during SMB negotiation. The referral is made before the connection is established. After ONTAP refers the SMB client to the target node, the connection is made, and the client accesses data through the referred LIF path from that point on. This allows the clients faster access to the data and avoids extra cluster communication.

Guidelines for using automatic node referrals with Mac OS clients

Mac OS X clients do not support SMB automatic node referrals, even though the Mac OS supports Microsoft's Distributed File System (DFS). Windows clients make a DFS referral request before connecting to an SMB share. ONTAP provides a referral to a data LIF found on the same node that hosts the requested data, which leads to improved client response times. Although the Mac OS supports DFS, Mac OS clients do not behave exactly like Windows clients in this area.

[NetApp Interoperability Matrix Tool](#)

Support for SMB automatic node referrals

Before you enable SMB automatic node referrals, you should be aware that certain

ONTAP functionality does not support referrals.

- The following types of volumes do not support SMB automatic node referrals:
 - Read-only members of a load-sharing mirror
 - Destination volume of a data-protection mirror
- Node referrals do not move alongside a LIF move.

If a client is using a referred connection over an SMB 2.x or SMB 3.0 connection and a data LIF moves nondisruptively, the client continues to use the same referred connection, even if the LIF is no longer local to the data.

- Node referrals do not move alongside a volume move.

If a client is using a referred connection over any SMB connection and a volume move occurs, the client continues to use the same referred connection, even if the volume is no longer located on the same node as the data LIF.

Enable or disable SMB automatic node referrals

You can enable SMB automatic node referrals to increase SMB client access performance. You can disable automatic node referrals if you do not want ONTAP to make referrals to SMB clients.

Before you begin

A CIFS server must be configured and running on the storage virtual machine (SVM).

About this task

The SMB automatic node referrals functionality is disabled by default. You can enable or disable this functionality on each SVM as required.

This option is available at the advanced privilege level.

Steps

1. Set the privilege level to advanced: `set -privilege advanced`
2. Enable or disable SMB automatic node referrals as required:

If you want SMB automatic node referrals to be...	Enter the following command...
Enabled	<code>vserver cifs options modify -vserver vserver_name -is-referral-enabled true</code>
Disabled	<code>vserver cifs options modify -vserver vserver_name -is-referral-enabled false</code>

The option setting takes effect for new SMB sessions. Clients with existing connection can utilize node referral only when their existing cache timeout expires.

3. Switch to the admin privilege level: `set -privilege admin`

Related information

[Available SMB server options](#)

Use statistics to monitor automatic node referral activity

To determine how many SMB connections are referred, you can monitor automatic node referral activity by using the `statistics` command. By monitoring referrals you can determine the extent to which automatic referrals are locating connections on nodes that host the shares and whether you should redistribute your data LIFs to provide better local access to shares on the CIFS server.

About this task

The `cifs` object provides several counters at the advanced privilege level that are helpful when monitoring SMB automatic node referrals:

- `node_referral_issued`

Number of clients that have been issued a referral to the share root's node after the client connected using a LIF hosted by a node different from the share root's node.

- `node_referral_local`

Number of clients that connected using a LIF hosted by the same node that hosts the share root. Local access generally provides optimal performance.

- `node_referral_not_possible`

Number of clients that have not been issued a referral to the node hosting the share root after connecting using a LIF hosted by a node different from the share root's node. This is because an active data LIF for the share root's node was not found.

- `node_referral_remote`

Number of clients that connected using a LIF hosted by a node different from the node that hosts the share root. Remote access might result in degraded performance.

You can monitor automatic node referral statistics on your storage virtual machine (SVM) by collecting and viewing data for a specific time period (a sample). You can view data from the sample if you do not stop data collection. Stopping data collection gives you a fixed sample. Not stopping data collection gives you the ability to get updated data that you can use to compare against previous queries. The comparison can help you identify performance trends.

To evaluate and use the information you gather from the `statistics` command, you should understand the distribution of clients in your environments.

Steps

1. Set the privilege level to advanced: `set -privilege advanced`
2. View automatic node referral statistics by using the `statistics` command.

This example views automatic node referral statistics by collecting and viewing data for a sampled time period:

- a. Start the collection: `statistics start -object cifs -instance vs1 -sample-id sample1`

```
Statistics collection is being started for Sample-id: sample1
```

- b. Wait for the desired collection time to elapse.
- c. Stop the collection: `statistics stop -sample-id sample1`

```
Statistics collection is being stopped for Sample-id: sample1
```

- d. View the automatic node referral statistics: `statistics show -sample-id sample1 -counter node`

```
Object: cifs
Instance: vs1
Start-time: 2/4/2013 19:27:02
End-time: 2/4/2013 19:30:11
Cluster: cluster1
```

Counter	Value
<hr/>	
node_name	node1
node_referral_issued	0
node_referral_local	1
node_referral_not_possible	2
node_referral_remote	2
...	
<hr/>	
node_name	node2
node_referral_issued	2
node_referral_local	1
node_referral_not_possible	0
node_referral_remote	2
...	

Output displays counters for all nodes participating in SVM vs1. For clarity, only output fields related to automatic node referral statistics are provided in the example.

3. Return to the admin privilege level: `set -privilege admin`

Performance monitoring setup

Monitor client-side SMB automatic node referral information using a Windows client

To determine what referrals are made from the client's perspective, you can use the Windows `dfsutil.exe` utility.

The Remote Server Administration Tools (RSAT) kit available with Windows 7 and later clients contains the `dfsutil.exe` utility. Using this utility, you can display information about the contents of the referral cache as well as view information about each referral that the client is currently using. You can also use the utility to clear the client's referral cache. For more information, consult the Microsoft TechNet Library.

Provide folder security on shares with access-based enumeration

Provide folder security on shares with access-based enumeration overview

When access-based enumeration (ABE) is enabled on an SMB share, users who do not have permission to access a folder or file contained within the share (whether through individual or group permission restrictions) do not see that shared resource displayed in their environment, although the share itself remains visible.

Conventional share properties allow you to specify which users (individually or in groups) have permission to view or modify files or folders contained within the share. However, they do not allow you to control whether folders or files within the share are visible to users who do not have permission to access them. This could pose problems if the names of these folders or files within the share describe sensitive information, such as the names of customers or products under development.

Access-based enumeration (ABE) extends share properties to include the enumeration of files and folders within the share. ABE therefore enables you to filter the display of files and folders within the share based on user access rights. That is, the share itself would be visible to all users, but files and folders within the share could be displayed to or hidden from designated users. In addition to protecting sensitive information in your workplace, ABE enables you to simplify the display of large directory structures for the benefit of users who do not need access to your full range of content. For example, the share itself would be visible to all users, but files and folders within the share could be displayed or hidden.

Learn about [Performance impact when using SMB/CIFS Access Based Enumeration](#).

Enable or disable access-based enumeration on SMB shares

You can enable or disable access-based enumeration (ABE) on SMB shares to allow or prevent users from seeing shared resources that they do not have permission to access.

About this task

By default, ABE is disabled.

Steps

1. Perform one of the following actions:

If you want to...	Enter the command...
Enable ABE on a new share	vserver cifs share create -vserver vserver_name -share-name share_name -path path -share-properties access-based-enumeration You can specify additional optional share settings and additional share properties when you create an SMB share. For more information, see the man page for the vserver cifs share create command.
Enable ABE on an existing share	vserver cifs share properties add -vserver vserver_name -share-name share_name -share-properties access-based-enumeration Existing share properties are preserved. The ABE share property is added to the existing list of share properties.
Disable ABE on an existing share	vserver cifs share properties remove -vserver vserver_name -share-name share_name -share-properties access-based-enumeration Other share properties are preserved. Only the ABE share property is removed from the list of share properties.

2. Verify that the share configuration is correct by using the vserver cifs share show command.

Examples

The following example creates an ABE SMB share named “sales” with a path of /sales on SVM vs1. The share is created with access-based-enumeration as a share property:

```

cluster1::> vserver cifs share create -vserver vs1 -share-name sales -path
/sales -share-properties access-based-
enumeration,oplocks,browsable,changenotify

cluster1::> vserver cifs share show -vserver vs1 -share-name sales

          Vserver: vs1
          Share: sales
CIFS Server NetBIOS Name: VS1
          Path: /sales
Share Properties: access-based-enumeration
                  oplocks
                  browsable
                  changenotify
Symlink Properties: enable
File Mode Creation Mask: -
Directory Mode Creation Mask: -
Share Comment: -
Share ACL: Everyone / Full Control
File Attribute Cache Lifetime: -
Volume Name: -
Offline Files: manual
Vscan File-Operations Profile: standard

```

The following example adds the `access-based-enumeration` share property to an SMB share named “`data2`”:

```

cluster1::> vserver cifs share properties add -vserver vs1 -share-name
data2 -share-properties access-based-enumeration

cluster1::> vserver cifs share show -vserver vs1 -share-name data2 -fields
share-name,share-properties
server  share-name share-properties
-----
vs1      data2      oplocks,browsable,changenotify,access-based-enumeration

```

Related information

[Adding or removing share properties on an existing SMB share](#)

[Enable or disable access-based enumeration from a Windows client](#)

You can enable or disable access-based enumeration (ABE) on SMB shares from a Windows client, which allows you to configure this share setting without needing to connect to the CIFS server.

The abecmd utility is not available in new versions of Windows Server and Windows clients. It was released as part of Windows Server 2008. Support ended for Windows Server 2008 on January 14, 2020.

Steps

1. From a Windows client that supports ABE, enter the following command: `abecmd [/enable | /disable] [/server CIFS_server_name] {/all | share_name}`

For more information about the abecmd command, see your Windows client documentation.

NFS and SMB file and directory naming dependencies

NFS and SMB file and directory naming dependencies overview

File and directory naming conventions depend on both the network clients' operating systems and the file-sharing protocols, in addition to language settings on the ONTAP cluster and clients.

The operating system and the file-sharing protocols determine the following:

- Characters a file name can use
- Case-sensitivity of a file name

ONTAP supports multi-byte characters in file, directory, and qtree names, depending on the ONTAP release.

Characters a file or directory name can use

If you are accessing a file or directory from clients with different operating systems, you should use characters that are valid in both operating systems.

For example, if you use UNIX to create a file or directory, do not use a colon (:) in the name because the colon is not allowed in MS-DOS file or directory names. Because restrictions on valid characters vary from one operating system to another, see the documentation for your client operating system for more information about prohibited characters.

Case-sensitivity of file and directory names in a multiprotocol environment

File and directory names are case-sensitive for NFS clients and case-insensitive but case-preserving for SMB clients. You must understand what the implications are in a multiprotocol environment and the actions you might need to take when specifying the path while creating SMB shares and when accessing data within the shares.

If an SMB client creates a directory named `testdir`, both SMB and NFS clients display the file name as `testdir`. However, if an SMB user later tries to create a directory name `TESTDIR`, the name is not allowed because, to the SMB client, that name currently exists. If an NFS user later creates a directory named `TESTDIR`, NFS and SMB clients display the directory name differently, as follows:

- On NFS clients, you see both directory names as they were created, for example `testdir` and `TESTDIR`, because directory names are case-sensitive.

- SMB clients use the 8.3 names to distinguish between the two directories. One directory has the base file name. Additional directories are assigned an 8.3 file name.

- On SMB clients, you see `testdir` and `TESTDI~1`.
- ONTAP creates the `TESTDI~1` directory name to differentiate the two directories.

In this case, you must use the 8.3 name when specifying a share path while creating or modifying a share on a storage virtual machine (SVM).

Similarly for files, if an SMB client creates `test.txt`, both SMB and NFS clients display the file name as `text.txt`. However, if an SMB user later tries to create `Test.txt`, the name is not allowed because, to the SMB client, that name currently exists. If an NFS user later creates a file named `Test.txt`, NFS and SMB clients display the file name differently, as follows:

- On NFS clients, you see both file names as they were created, `test.txt` and `Test.txt`, because file names are case-sensitive.
- SMB clients use the 8.3 names to distinguish between the two files. One file has the base file name. Additional files are assigned an 8.3 file name.
 - On SMB clients, you see `test.txt` and `TEST~1.TXT`.
 - ONTAP creates the `TEST~1.TXT` file name to differentiate the two files.

If you have enabled or modified character mapping using the Vserver CIFS character-mapping commands, a normally case-insensitive Windows lookup becomes case-sensitive.

How ONTAP creates file and directory names

ONTAP creates and maintains two names for files or directories in any directory that has access from an SMB client: the original long name and a name in 8.3 format.

For file or directory names that exceed the eight character name or the three character extension limit (for files), ONTAP generates an 8.3-format name as follows:

- It truncates the original file or directory name to six characters, if the name exceeds six characters.
- It appends a tilde (~) and a number, one through five, to file or directory names that are no longer unique after being truncated.

If it runs out of numbers because there are more than five similar names, it creates a unique name that bears no relation to the original name.

- In the case of files, it truncates the file name extension to three characters.

For example, if an NFS client creates a file named `specifications.html`, the 8.3 format file name created by ONTAP is `specif~1.htm`. If this name already exists, ONTAP uses a different number at the end of the file name. For example, if an NFS client then creates another file named `specifications_new.html`, the 8.3 format of `specifications_new.html` is `specif~2.htm`.

How ONTAP handles multi-byte file, directory, and qtree names

Beginning with ONTAP 9.5, support for 4-byte UTF-8 encoded names enables the creation and display of file, directory, and tree names that include Unicode supplementary

characters outside the Basic Multilingual Plane (BMP). In earlier releases, these supplementary characters did not display correctly in multiprotocol environments.

To enable support for 4-byte UTF-8 encoded names, a new *utf8mb4* language code is available for the `vserver` and `volume` command families.

- You must create a new volume in one of the following ways:
 - Setting the `volume -language` option explicitly: `volume create -language utf8mb4 {...}`
 - Inheriting the `volume -language` option from an SVM that has been created with or modified for the `vserver [create|modify] -language utf8mb4 {...}``volume create {...}` option:
- You cannot modify existing volumes for `utf8mb4` support; you must create a new `utf8mb4`-ready volume, and then migrate the data using client-based copy tools.

You can update SVMs for `utf8mb4` support, but existing volumes retain their original language codes.

LUN names with 4-byte UTF-8 characters are not currently supported.

- Unicode character data is typically represented in Windows file systems applications using the 16-bit Unicode Transformation Format (UTF-16) and in NFS file systems using the 8-bit Unicode Transformation Format (UTF-8).

In releases prior to ONTAP 9.5, names including UTF-16 supplementary characters that were created by Windows clients were correctly displayed to other Windows clients but were not translated correctly to UTF-8 for NFS clients. Similarly, names with UTF-8 supplementary characters by created NFS clients were not translated correctly to UTF-16 for Windows clients.

- When you create file names on systems running ONTAP 9.4 or earlier that contain valid or invalid supplementary characters, ONTAP rejects the file name and returns an invalid file name error.

To avoid this issue, use only BMP characters in file names and avoid using supplementary characters, or upgrade to ONTAP 9.5 or later.

Beginning with ONTAP 9, Unicode characters are allowed in qtree names.

- You can use either the `volume qtree` command family or System Manager to set or modify qtree names.
- qtree names can include multi-byte characters in Unicode format, such as Japanese and Chinese characters.
- In releases before ONTAP 9.5, only BMP characters (that is, those that could be represented in 3 bytes) were supported.

In releases before ONTAP 9.5, the junction-path of the qtree's parent volume can contain qtree and directory names with Unicode characters. The `volume show` command displays these names correctly when the parent volume has a UTF-8 language setting. However, if the parent volume language is not one of the UTF-8 language settings, some parts of the junction-path are displayed using a numeric NFS alternate name.

- In 9.5 and later releases, 4-byte characters are supported in qtree names, provided that the qtree is in a volume enabled for `utf8mb4`.

Configure character mapping for SMB file name translation on volumes

NFS clients can create file names that contain characters that are not valid for SMB clients and certain Windows applications. You can configure character mapping for file name translation on volumes to allow SMB clients to access files with NFS names that would otherwise not be valid.

About this task

When files created by NFS clients are accessed by SMB clients, ONTAP looks at the name of the file. If the name is not a valid SMB file name (for example, if it has an embedded colon ":" character), ONTAP returns the 8.3 file name that is maintained for each file. However, this causes problems for applications that encode important information into long file names.

Therefore, if you are sharing a file between clients on different operating systems, you should use characters in the file names that are valid in both operating systems.

However, if you have NFS clients that create file names containing characters that are not valid file names for SMB clients, you can define a map that converts the invalid NFS characters into Unicode characters that both SMB and certain Windows applications accept. For example, this functionality supports the CATIA MCAD and Mathematica applications as well as other applications that have this requirement.

You can configure character mapping on a volume-by-volume basis.

You must keep the following in mind when configuring character mapping on a volume:

- Character mapping is not applied across junction points.

You must explicitly configure character mapping for each junction volume.

- You must make sure that the Unicode characters that are used to represent invalid or illegal characters are characters that do not normally appear in file names; otherwise, unwanted mappings occur.

For example, if you try to map a colon (:) to a hyphen (-) but the hyphen (-) was used in the file name correctly, a Windows client trying to access a file named "a-b" would have its request mapped to the NFS name of "a:b" (not the desired outcome).

- After applying character mapping, if the mapping still contains an invalid Windows character, ONTAP falls back to Windows 8.3 file names.
- In FPolicy notifications, NAS audit logs, and security trace messages, the mapped file names are shown.
- When a SnapMirror relation of type DP is created, the source volume's character mapping is not replicated on the destination DP volume.
- Case sensitivity: Because the mapped Windows names turn into NFS names, the lookup of the names follows NFS semantics. That includes the fact that NFS lookups are case-sensitive. This means that the applications accessing mapped shares must not rely on Windows case-insensitive behavior. However, the 8.3 name is available, and that is case-insensitive.
- Partial or invalid mappings: After mapping a name to return to clients doing directory enumeration ("dir"), the resulting Unicode name is checked for Windows validity. If that name still has invalid characters in it, or if it is otherwise invalid for Windows (e.g. it ends in ":" or blank) the 8.3 name is returned instead of the invalid name.

Step

1. Configure character mapping: +

```
vserver cifs character-mapping create -vserver vserver_name -volume volume_name  
-mapping mapping_text, ... +
```

The mapping consists of a list of source-target character pairs separated by “.”. The characters are Unicode characters entered using hexadecimal digits. For example: 3C:E03C. +

The first value of each `mapping_text` pair that is separated by a colon is the hexadecimal value of the NFS character you want to translate, and the second value is the Unicode value that SMB uses. The mapping pairs must be unique (a one-to-one mapping should exist).

- Source mapping +

The following table shows the permissible Unicode character set for source mapping:

+

Unicode character	Printed character	Description
0x01-0x19	Not applicable	Non-printing control characters
0x5C	\	Backslash
0x3A	:	Colon
0x2A	*	Asterisk
0x3F	?	Question mark
0x22	"	Quotation mark
0x3C	<	Less than
0x3E	>	Greater than
0x7C		Vertical line
0xB1	±	Plus-minus sign

- Target mapping

You can specify target characters in the “Private Use Area” of Unicode in the following range: U+E0000...U+F8FF.

Example

The following command creates a character mapping for a volume named “data” on storage virtual machine (SVM) vs1:

```

cluster1::> vserver cifs character-mapping create -volume data -mapping
3c:e17c,3e:f17d,2a:f745
cluster1::> vserver cifs character-mapping show

Vserver          Volume Name   Character Mapping
-----
vs1              data          3c:e17c, 3e:f17d, 2a:f745

```

Commands for managing character mappings for SMB file name translation

You can manage character mapping by creating, modifying, displaying information about, or deleting file character mappings used for SMB file name translation on FlexVol volumes.

If you want to...	Use this command...
Create new file character mappings	vserver cifs character-mapping create
Display information about file character mappings	vserver cifs character-mapping show
Modify existing file character mappings	vserver cifs character-mapping modify
Delete file character mappings	vserver cifs character-mapping delete

For more information, see the man page for each command.

[Configuring character mapping for SMB file name translation on volumes](#)

Provide S3 client access to NAS data

S3 multiprotocol overview

Beginning with ONTAP 9.12.1, you can enable clients running the S3 protocol to access the same data that are being served to clients that use the NFS and SMB protocols without reformatting. This capability allows NAS data to continue to be served to NAS clients, while presenting object data to S3 clients running S3 applications (such as data mining and artificial intelligence).

S3 multiprotocol functionality addresses two use cases:

1. Access to existing NAS data using S3 clients

If your existing data was created using traditional NAS clients (NFS or SMB) and is located on NAS volumes (FlexVol or FlexGroup volumes), you can now use analytical tools on S3 clients to access this data.

2. Backend storage for modern clients capable of performing I/O using both NAS and S3 protocols

You can now provide integrated access for applications such Spark and Kafka that can read and write the same data using both NAS and S3 protocols.

How S3 multiprotocol works

ONTAP multiprotocol allows you to present the same data set as a file hierarchy or as objects in a bucket. To do so, ONTAP creates “S3 NAS buckets” that allow S3 clients to create, read, delete, and enumerate files in NAS storage using S3 object requests. This mapping conforms to the NAS security configuration, observing file and directory access permissions as well as writing to the security audit trail as necessary.

This mapping is accomplished by presenting a specified NAS directory hierarchy as an S3 bucket. Each file in the directory hierarchy is represented as an S3 object whose name is relative from the mapped directory downwards, with directory boundaries represented by the slash character (/).

Normal ONTAP-defined S3 users can access this storage, as governed by the bucket policies defined for the bucket that maps to the NAS directory. For this to be possible, mappings must be defined between the S3 users and SMB/NFS users. The credentials of the SMB/NFS user will be used for the NAS permissions checking and included in any audit records resulting from these accesses.

When created by SMB or NFS clients, a file is immediately placed in a directory, and therefore visible to clients, before any data is written to it. S3 clients expect different semantics, in which the new object is not visible in the namespace until all its data has been written. This mapping of S3 to NAS storage creates files using S3 semantics, keeping the files invisible externally until the S3 creation command completes.

Data protection for S3 NAS buckets

S3 NAS “buckets” are simply mappings of NAS data for S3 clients, they are not standard S3 buckets. Therefore, there is no need to protect S3 NAS buckets using NetApp S3 SnapMirror functionality. Instead, you can replicate source SVMs containing S3 NAS buckets using SVM DR, a standard SnapMirror data protection relationship with destination SVMs. SVM DR is the only supported SnapMirror replication method with S3 multiprotocol. SnapMirror Synchronous is not supported.

Learn about [SnapMirror SVM replication](#).

Auditing for S3 NAS buckets

Because S3 NAS buckets are not conventional S3 buckets, S3 audit cannot be configured to audit access on them. Learn more about [S3 audit](#).

Nonetheless, the NAS files and directories that are mapped in S3 NAS buckets can be audited for access events using conventional ONTAP audit procedures. S3 operations can therefore trigger NAS audit events, with the following exceptions:

- If S3 client access is denied by the S3 policy configuration (group or bucket policy), NAS audit for the event is not initiated. This is because S3 permissions are checked before SVM audit checks can be made.
- If the target file of an S3 Get request is 0 size, 0 content is returned to the Get request and the Read access is not logged.

- If the target file of an S3 Get request is in a folder for which the user has no traverse permission, the access attempt fails and the event is not logged.

Learn about [auditing NAS events on SVMs](#).

S3 and NAS interoperability

ONTAP S3 NAS buckets support standard NAS and S3 functionality except as listed here.

NAS functionality not currently supported by S3 NAS buckets

FabricPool capacity tier

S3 NAS buckets cannot be configured as a capacity tier for FabricPool.

S3 functionality not currently supported by S3 NAS buckets

AWS user metadata

- Key-values pairs received as part of S3 user-metadata are not stored on disk along with object data in the current release.
- Request headers with the prefix "x-amz-meta" are ignored.

AWS Tags

- On PUT object and Multipart Initiate requests, headers with the prefix "x-amz-tagging" are ignored.
- Requests to update tags on an existing file (i.e. a Put, Get, and Delete requests with the ?tagging query-string) are rejected with an error.

Versioning

It is not possible to specify versioning in the bucket mapping configuration.

- Requests that include non-null version specifications (the versionId=xyz query-string) receive error responses.
- Requests to affect the versioning state of a bucket are rejected with errors.

Multipart operations

The following operations are not supported:

- AbortMultipartUpload
- CompleteMultipartUpload
- CreateMultipartUpload
- ListMultipartUpload

NAS data requirements for S3 client access

It is important to understand that there are some inherent incompatibilities when mapping NAS files and directories for S3 access. It might be necessary to adjust NAS file hierarchies before serving them using S3 NAS buckets.

An S3 NAS bucket provides S3 access to a NAS directory by mapping that directory using S3 bucket syntax, and the files in the directory tree are viewed as objects. The object names are the slash-delimited pathnames of the files relative to the directory specified in the S3 bucket configuration.

This mapping imposes some requirements when files and directories are served using S3 NAS buckets:

- S3 names are limited to 1024 bytes, so files with longer pathnames are not accessible using S3.
- File and directory names are limited to 255 characters, so an object name cannot have more than 255 consecutive non-slash ('/') characters
- An SMB pathname that is delimited by backslash ('\') characters will appear to s3 as an object name containing forward-slash ('/') characters instead.
- Some pairs of legal S3 object names cannot coexist in the mapped NAS directory tree. For example, the legal S3 object names “part1/part2” and “part1/part2/part3” map to files that cannot simultaneously exist in the NAS directory tree, as “part1/part2” is a file in the first name and a directory in the other.
 - If “part1/part2” is an existing file, an S3 creation of “part1/part2/part3” will fail.
 - If “part1/part2/part3” is an existing file, an S3 creation or deletion of “part1/part2” will fail.
 - An S3 object creation that matches the name of an existing object replaces the pre-existing object (in unversioned buckets); that holds in NAS but requires an exact match. The examples above will not cause removal of the existing object because while the names collide, they do not match.

While an object store is designed to support a very large number of arbitrary names, a NAS directory structure can experience performance problems if a very large number of names are placed in one directory. In particular, names with no slash ('/') characters in them will all be placed into the root directory of the NAS mapping. Applications that make extensive use of names that are not “NAS-friendly” would be better hosted on an actual object store bucket rather than a NAS mapping.

Enable S3 protocol access to NAS data

Enabling S3 protocol access consists of ensuring that a NAS-enabled SVM meets the same requirements as an S3-enabled server, including adding an object store server, and verifying networking and authentication requirements.

For new ONTAP installations, it is recommended that you enable S3 protocol access to an SVM after configuring it to serve NAS data to clients. To learn about NAS protocol configuration, see:

- [NFS configuration](#)
- [SMB configuration](#)

Before you begin

The following must be configured before enabling the S3 protocol:

- The S3 protocol and the desired NAS protocols – NFS, SMB, or both – are licensed.
- An SVM is configured for the desired NAS protocols.
- NFS and/or SMB servers exist.
- DNS and any other required services are configured.
- NAS data is being exported or shared to client systems.

About this task

A Certificate Authority (CA) certificate is required to enable HTTPS traffic from S3 clients to the S3-enabled SVM. CA certificates from three sources can be used:

- A new ONTAP self-signed certificate on the SVM.

- An existing ONTAP self-signed certificate on the SVM.
- A third-party certificate.

You can use the same data LIFs for the S3/NAS bucket that you use for serving NAS data. If specific IP addresses are required, see [Create data LIFs](#). An S3 service data policy is required to enable S3 data traffic on LIFs; you can modify the SVM's existing service policy to include S3.

When you create the S3 object server, you should be prepared to enter the S3 server name as a Fully Qualified Domain Name (FQDN), which clients will use for S3 access. The S3 server FQDN must not begin with a bucket name.

System Manager

1. Enable S3 on a storage VM with NAS protocols configured.
 - a. Click **Storage > Storage VMs**, select a NAS-ready storage VM, click Settings, and then click  under S3.
 - b. Select the certificate type. Whether you select system-generated certificate or one of your own, it will be required for client access.
 - c. Enter the network interfaces.
2. If you selected the system-generated certificate, you see the certificate information when the new storage VM creation is confirmed. Click **Download** and save it for client access.
 - The secret key will not be displayed again.
 - If you need the certificate information again: click **Storage > Storage VMs**, select the storage VM, and click **Settings**.

CLI

1. Verify that the S3 protocol is allowed on the SVM:

```
vserver show -fields allowed-protocols
```

2. Record the public key certificate for this SVM.

If a new ONTAP self-signed certificate is needed, see [Create and install a CA certificate on the SVM](#).

3. Update the service data policy

- a. Display the service data policy for the SVM

```
network interface service-policy show -vserver svm_name
```

- b. Add the data-core and data-s3-server services if they are not present.

```
network interface service-policy add-service -vserver svm_name -policy
policy_name -services data-core,data-s3-server
```

4. Verify that the data LIFs on the SVM meet your requirements:

```
network interface show -vserver svm_name
```

5. Create the S3 server:

```
vserver object-store-server create -vserver svm_name -object-store-server
s3_server_fqdn -certificate-name ca_cert_name -comment text
[additional_options]
```

You can specify additional options when creating the S3 server or at any time later.

- HTTPS is enabled by default on port 443. You can change the port number with the -secure-listener -port option.
When HTTPS is enabled, CA certificates are required for proper integration with SSL/TLS.
- HTTP is disabled by default; when enabled, the server listens on port 80. You can enable it with the -is-http-enabled option or change the port number with the -listener-port option.
When HTTP is enabled, all the request and responses are sent over the network in clear text.

6. Verify that S3 is configured as desired:

```
vserver object-store-server show
```

Example

The following command verifies the configuration values of all object storage servers:

```
cluster1::> vserver object-store-server show
```

```
Vserver: vs1

Object Store Server Name: s3.example.com
Administrative State: up
Listener Port For HTTP: 80
Secure Listener Port For HTTPS: 443
HTTP Enabled: false
HTTPS Enabled: true
Certificate for HTTPS Connections: svm1_ca
Comment: Server comment
```

Create S3 NAS bucket

An S3 NAS buckets is a mapping between an S3 bucket name and a NAS path. S3 NAS buckets allow you to provide S3 access to any part of an SVM namespace having existing volumes and directory structure.

Before you begin

- An S3 object server is configured in an SVM containing NAS data.
- The NAS data conforms to the [requirements for S3 client access](#).

About this task

You can configure S3 NAS buckets to specify any set of files and directories within the root directory of the SVM.

You can also set bucket policies that allow or disallow access to NAS data based on any combination of these parameters:

- Files and directories
- User and group permissions
- S3 operations

For example, you might want separate bucket policies that grant read-only data access to a large group of users, and another that allows a limited group to perform operations on a subset of that data.

Because S3 NAS “buckets” are mappings and not S3 buckets, the following properties of standard S3 buckets don’t apply to S3 NAS buckets.

- **aggr-list \ aggr-list-multiplier \ storage-service-level \ volume \ size \ exclude-aggr-list \ qos-policy-group**
No volumes or qtree are created when configuring S3 NAS buckets.
- **role \ is -protected \ is -protected-on-ontap \ is -protected-on-cloud**
S3 NAS buckets are not protected or mirrored using S3 SnapMirror, but will instead be using regular SnapMirror protection available at volume granularity.

- **versioning-state**

NAS volumes usually have Snapshot technology available to save different versions. However, versioning is not currently available in S3 NAS buckets.

- **logical-used \ object-count**

Equivalent statistics are available for NAS volumes through the volume commands.

System Manager

Add a new S3 NAS bucket on an NAS-enabled storage VM.

1. Click **Storage > Buckets**, then click **Add**.
2. Enter a name for the S3 NAS bucket and select the storage VM, do not enter a size, then click **More Options**.
3. Enter a valid path name or click **Browse** to select from a list of valid path names.
When you enter a valid pathname, options that are not relevant to S3 NAS configuration are hidden.
4. If you have already mapped S3 users to NAS users and created groups, you can configure their permissions, then click **Save**.
You must have already mapped S3 users to NAS users before configuring permissions in this step.

Otherwise, click **Save** to complete S3 NAS bucket configuration.

CLI

Create an S3 NAS bucket in an SVM containing NAS filesystems.

```
vserver object-store-server bucket create -vserver svm_name -bucket  
bucket_name -type nas -nas-path junction_path [-comment text]
```

Example:

```
cluster1::> vserver object-store-server bucket create -bucket testbucket -type  
nas -path /vol1
```

Enable S3 client users

To enable S3 client users to access NAS data, you must map S3 user names to corresponding NAS users, then grant them permission to access the NAS data using bucket service policies.

Before you begin

User names for client access – LINUX/UNIX, Windows and S3 client users – must already exist.

About this task

Mapping an S3 user name to a corresponding LINUX/UNIX or Windows user allows authorization checks on the NAS files to be honored when those files are accessed by S3 clients. S3 to NAS mappings are specified by providing an S3 user name *Pattern*, which can be expressed as a single name or a POSIX regular expression, and a LINUX/UNIX or Windows user name *Replacement*.

In case there is no name-mapping present, default name-mapping will be used, where the S3 user name itself will be used as the UNIX user name and Windows user name. You can modify the UNIX and Windows default user name mappings with the `vserver object-store-server modify` command.

Only local name-mapping configuration is supported; LDAP is not supported.

After S3 users are mapped to NAS users, you can grant permissions to users specifying the resources (directories and files) to which they have access and the actions they are allowed or not allowed to perform there.

System Manager

1. Create local name mappings for UNIX or Windows clients (or both).
 - a. Click **Storage > Buckets**, then select the S3/NAS-enabled storage VM.
 - b. Select **Settings**, then click → in **Name Mapping** (under **Host Users and Groups**).
 - c. In the **S3 to Windows** or **S3 to UNIX** tiles (or both), click **Add**, then enter the desired **Pattern** (S3) and **Replacement** (NAS) user names.
2. Create a bucket policy to provide client access.
 - a. Click **Storage > Buckets**, click : next to the desired S3 bucket, then click **Edit**.
 - b. Click **Add** and supply the desired values.
 - **Principal** - Provide S3 user names or use the default (all users).
 - **Effect** - Select **Allow** or **Deny**.
 - **Actions** - Enter actions for these users and resources. The set of resource operations that the object store server currently supports for S3 NAS buckets are: GetObject, PutObject, DeleteObject, ListBucket, GetBucketAcl, GetObjectAcl, GetObjectTagging, PutObjectTagging, DeleteObjectTagging, GetBucketLocation, GetBucketVersioning, PutBucketVersioning and ListBucketVersions. Wildcards are accepted for this parameter.
 - **Resources** - Enter folder or file paths in which the actions are allowed or denied, or use the defaults (root directory of the bucket).

CLI

1. Create local name mappings for UNIX or Windows clients (or both).

```
vserver name-mapping create -vserver svm_name> -direction {s3-win|s3-unix} -position integer -pattern s3_user_name -replacement nas_user_name
```

- **-position** - priority number for mapping evaluation; enter 1 or 2.
- **-pattern** - an S3 user name or a regular expression
- **-replacement** - a windows or unix user name

Examples

```
vserver name-mapping create -direction s3-win -position 1 -pattern s3_user_1 -replacement win_user_1
```

```
vserver name-mapping create -direction s3-unix -position 2 -pattern s3_user_1 -replacement unix_user_1
```

2. Create a bucket policy to provide client access.

```
vserver object-store-server bucket policy add-statement -vserver svm_name -bucket bucket_name -effect {deny|allow} -action list_of_actions -principal list_of_users_or_groups -resource [-sid alphanumeric_text]
```

- **-effect {deny|allow}** - specifies whether access is allowed or denied when a user requests an action.
- **-action <Action>, ...** - specifies resource operations that are allowed or denied. The set of resource operations that the object store server currently supports for S3 NAS buckets are: GetObject, PutObject, DeleteObject, ListBucket, GetBucketAcl, GetObjectAcl, GetObjectTagging, PutObjectTagging, DeleteObjectTagging, GetBucketLocation, GetBucketVersioning, PutBucketVersioning and ListBucketVersions. Wildcards are accepted for this parameter.

- `-principal <Objectstore Principal>`, ... - validates the user requesting access against the object store server users or groups specified in this parameter.
 - An object store server group is specified by adding a prefix group/ to the group name.
 - `-principal -` (the hyphen character) grants access to all users.
- `-resource <text>`, ... - specifies the bucket, folder, or object for which allow/deny permissions are set. Wildcards are accepted for this parameter.
- `[-sid <SID>]` - specifies an optional text comment for the object store server bucket policy statement.

Examples

```
cluster1::> vserver object-store-server bucket policy add-statement -bucket testbucket -effect allow -action GetObject,PutObject,DeleteObject,ListBucket,GetBucketAcl,GetObjectAcl,GetBucketLocation,GetBucketPolicy,PutBucketPolicy,DeleteBucketPolicy -principal user1 -resource testbucket,testbucket/* sid "FullAccessForUser1"

cluster1::> vserver object-store-server bucket policy statement create -vserver vs1 -bucket bucket1 -effect allow -action GetObject -principal - -resource bucket1/readme/* -sid "ReadAccessToReadmeForAllUsers"
```

SMB configuration for Microsoft Hyper-V and SQL Server

SMB configuration for Microsoft Hyper-V and SQL Server overview

ONTAP features allow you to enable nondisruptive operations for two Microsoft applications over the SMB protocol: Microsoft Hyper-V and Microsoft SQL Server.

You should use these procedures if you want to implement SMB nondisruptive operations under the following circumstances:

- Basic SMB protocol file access has been configured.
- You want to enable SMB 3.0 or later file shares residing in SVMs to store the following objects:
 - Hyper-V virtual machine files
 - SQL Server system databases

Related information

For additional information about ONTAP technology and interaction with external services, see these Technical Reports (TRs):

[NetApp Technical Report 4172: Microsoft Hyper-V over SMB 3.0 with ONTAP Best Practices](#)

[NetApp Technical Report 4369: Best Practices for Microsoft SQL Server and SnapManager 7.2 for SQL Server with Clustered Data ONTAP](#)

Configure ONTAP for Microsoft Hyper-V and SQL Server over SMB solutions

You can use continuously available SMB 3.0 and later file shares to store Hyper-V virtual machine files or SQL Server system databases and user databases on volumes residing in SVMs, while at the same time providing nondisruptive operations (NDOs) for both

planned and unplanned events.

Microsoft Hyper-V over SMB

To create a Hyper-V over SMB solution, you must first configure ONTAP to provide storage services for Microsoft Hyper-V servers. Additionally, you must also configure Microsoft clusters (if using a clustered configuration), Hyper-V servers, continuously available SMB 3.0 connections to the shares hosted by the CIFS server, and, optionally, backup services to protect the virtual machine files that are stored on SVM volumes.

The Hyper-V servers must be configured on Windows 2012 Server or later. Both stand-alone and clustered Hyper-V server configurations are supported.

- For information about creating Microsoft clusters and Hyper-V servers, see the Microsoft web site.
- SnapManager for Hyper-V is a host-based application that facilitates rapid, Snapshot copy-based backup services, designed to integrate with Hyper-V over SMB configurations.

For information about using SnapManager with Hyper-V over SMB configurations, see *SnapManager for Hyper-V Installation and Administration Guide*.

Microsoft SQL Server over SMB

To create a SQL Server over SMB solution, you must first configure ONTAP to provide storage services for the Microsoft SQL Server application. Additionally, you must also configure Microsoft clusters (if using a clustered configuration). You would then install and configure SQL Server on the Windows servers and create continuously available SMB 3.0 connections to the shares hosted by the CIFS server. You can optionally configure backup services to protect the database files that are stored on SVM volumes.

SQL Server must be installed and configured on Windows 2012 Server or later. Both stand-alone and clustered configurations are supported.

- For information about creating Microsoft clusters and installing and configuring SQL Server, see the Microsoft web site.
- SnapCenter Plug-in for Microsoft SQL Server is a host-based application that facilitates rapid, Snapshot copy-based backup services, designed to integrate with SQL Server over SMB configurations.

For information about using SnapCenter Plug-in for Microsoft SQL Server, see the [SnapCenter Plug-in for Microsoft SQL Server](#) document.

Nondisruptive operations for Hyper-V and SQL Server over SMB

What nondisruptive operations for Hyper-V and SQL Server over SMB means

Nondisruptive operations for Hyper-V and SQL Server over SMB refers to the combination of capabilities that enable the application servers and the contained virtual machines or databases to remain online and to provide continuous availability during many administrative tasks. This includes both planned and unplanned downtime of the storage infrastructure.

Supported nondisruptive operations for application servers over SMB include the following:

- Planned takeover and giveback
- Unplanned takeover
- Upgrade
- Planned aggregate relocation (ARL)
- LIF migration and failover
- Planned volume move

Protocols that enable nondisruptive operations over SMB

Along with the release of SMB 3.0, Microsoft has released new protocols to provide the capabilities necessary to support nondisruptive operations for Hyper-V and SQL Server over SMB.

ONTAP uses these protocols when providing nondisruptive operations for application servers over SMB:

- SMB 3.0
- Witness

Key concepts about nondisruptive operations for Hyper-V and SQL Server over SMB

There are certain concepts about nondisruptive operations (NDOs) that you should understand before you configure your Hyper-V or SQL Server over SMB solution.

- **Continuously available share**

An SMB 3.0 share that has the continuously available share property set. Clients connecting through continuously available shares can survive disruptive events such as takeover, giveback, and aggregate relocation.

- **Node**

A single controller that is a member of a cluster. To distinguish between the two nodes in an SFO pair, one node is sometimes called the *local node* and the other node is sometimes called the *partner node* or *remote node*. The primary owner of the storage is the local node. The secondary owner, which takes control of the storage when the primary owner fails, is the partner node. Each node is the primary owner of its storage and secondary owner for its partner's storage.

- **Nondisruptive aggregate relocation**

The ability to move an aggregate between partner nodes within an SFO pair in a cluster without interrupting client applications.

- **Nondisruptive failover**

See *Takeover*.

- **Nondisruptive LIF migration**

The ability to perform a LIF migration without interrupting client applications that are connected to the cluster through that LIF. For SMB connections, this is only possible for clients that connect using SMB 2.0 or later.

- **Nondisruptive operations**

The ability to perform major ONTAP management and upgrade operations as well as withstand node failures without interrupting client applications. This term refers to the collection of nondisruptive takeover, nondisruptive upgrade, and nondisruptive migration capabilities as a whole.

- **Nondisruptive upgrade**

The ability to upgrade node hardware or software without application interruption.

- **Nondisruptive volume move**

The ability to move a volume freely throughout the cluster without interrupting any applications that are using the volume. For SMB connections, all versions of SMB support nondisruptive volume moves.

- **Persistent handles**

A property of SMB 3.0 that allows continuously available connections to transparently reconnect to the CIFS server in the event of a disconnection. Similar to durable handles, persistent handles are maintained by the CIFS server for a period of time after communication to the connecting client is lost. However, persistent handles have more resilience than durable handles. In addition to giving the client a chance to reclaim the handle within a 60-second window after reconnecting, the CIFS server denies access to any other clients requesting access to the file during that 60-second window.

Information about persistent handles is mirrored on the SFO partner's persistent storage, which allows clients with disconnected persistent handles to reclaim the durable handles after an event where the SFO partner takes ownership of the node's storage. In addition to providing nondisruptive operations in the event of LIF moves (which durable handles support), persistent handles provide nondisruptive operations for takeover, giveback, and aggregate relocation.

- **SFO giveback**

Returning aggregates to their home locations when recovering from a takeover event.

- **SFO pair**

A pair of nodes whose controllers are configured to serve data for each other if one of the two nodes stops functioning. Depending on the system model, both controllers can be in a single chassis, or the controllers can be in separate chassis. Known as an HA pair in a two-node cluster.

- **Takeover**

The process by which the partner takes control of the storage when the primary owner of that storage fails. In the context of SFO, failover and takeover are synonymous.

How SMB 3.0 functionality supports nondisruptive operations over SMB shares

SMB 3.0 provides crucial functionality that enables support for nondisruptive operations for Hyper-V and SQL Server over SMB shares. This includes the continuously-available share property and a type of file handle known as a *persistent handle* that allow SMB clients to reclaim file open state and transparently reestablish SMB connections.

Persistent handles can be granted to SMB 3.0 capable clients that connect to a share with the continuously

available share property set. If the SMB session is disconnected, the CIFS server retains information about persistent handle state. The CIFS server blocks other client requests during the 60-second period in which the client is allowed to reconnect, thus allowing the client with the persistent handle to reclaim the handle after a network disconnection. Clients with persistent handles can reconnect by using one of the data LIFs on the storage virtual machine (SVM), either by reconnecting through the same LIF or through a different LIF.

Aggregate relocation, takeover, and giveback all occur between SFO pairs. To seamlessly manage the disconnection and reconnection of sessions with files that have persistent handles, the partner node maintains a copy of all persistent handle lock information. Whether the event is planned or unplanned, the SFO partner can nondisruptively manage the persistent handle reconnects. With this new functionality, SMB 3.0 connections to the CIFS server can transparently and nondisruptively fail over to another data LIF assigned to the SVM in what traditionally has been disruptive events.

Although the use of persistent handles allows the CIFS server to transparently fail over SMB 3.0 connections, if a failure causes the Hyper-V application to fail over to another node in the Windows Server cluster, the client has no way to reclaim the file handles of these disconnected handles. In this scenario, file handles in the disconnected state can potentially block access of the Hyper-V application if it is restarted on a different node. “Failover Clustering” is a part of SMB 3.0 that addresses this scenario by providing a mechanism to invalidate stale, conflicting handles. Using this mechanism, a Hyper-V cluster can recover quickly when Hyper-V cluster nodes fail.

What the Witness protocol does to enhance transparent failover

The Witness protocol provides enhanced client failover capabilities for SMB 3.0 continuously available shares (CA shares). Witness facilitates faster failover because it bypasses the LIF failover recovery period. It notifies applications servers when a node is unavailable without needing to wait for the SMB 3.0 connection to time out.

The failover is seamless, with applications running on the client not being aware that a failover occurred. If Witness is not available, failover operations still occur successfully, but failover without Witness is less efficient.

Witness enhanced failover is possible when the following requirements are met:

- It can only be used with SMB 3.0-capable CIFS servers that have SMB 3.0 enabled.
- The shares must use SMB 3.0 with the continuous availability share property set.
- The SFO partner of the node to which the application servers are connected must have at least one operational data LIF assigned to the storage virtual machine (SVM) hosting data for the application servers.

The Witness protocol operates between SFO pairs. Because LIFs can migrate to any node within the cluster, any node might need to be the witness for its SFO partner. The Witness protocol cannot provide rapid failover of SMB connections on a given node if the SVM hosting data for the application servers does not have an active data LIF on the partner node. Therefore, every node in the cluster must have at least one data LIF for each SVM hosting one of these configurations.

- The application servers must connect to the CIFS server by using the CIFS server name that is stored in DNS instead of by using individual LIF IP addresses.

How the Witness protocol works

ONTAP implements the Witness protocol by using a node’s SFO partner as the witness. In the event of a failure, the partner quickly detects the failure and notifies the SMB client.

The Witness protocol provides enhanced failover using the following process:

1. When the application server establishes a continuously available SMB connection to Node1, the CIFS server informs the application server that Witness is available.
2. The application server requests the IP addresses of the Witness server from Node1 and receives a list of Node2 (the SFO partner) data LIF IP addresses assigned to the storage virtual machine (SVM).
3. The application server chooses one of the IP addresses, creates a Witness connection to Node2, and registers to be notified if the continuously available connection on Node1 must move.
4. If a failover event occurs on Node1, Witness facilitates failover events, but is not involved with giveback.
5. Witness detects the failover event and notifies the application server through the Witness connection that the SMB connection must move to Node2.
6. The application server moves the SMB session to Node2 and recovers the connection without interruption to client access.

Share-based backups with Remote VSS

Share-based backups with Remote VSS overview

You can use Remote VSS to perform share-based backups of Hyper-V virtual machine files that are stored on a CIFS server.

Microsoft Remote VSS (Volume Shadow Copy Services) is an extension of the existing Microsoft VSS infrastructure. Previously, VSS could be used for backup services only for data stored on local disk. This limited the use of VSS to applications that store data either on a local disk or on SAN-based storage. With Remote VSS, Microsoft has extended the VSS infrastructure to support the shadow copying of SMB shares. Server applications such as Hyper-V are now storing VHD files on SMB file shares. With these new extensions, it is possible to take application consistent shadow copies for virtual machines that store data and configuration files on shares.

Remote VSS concepts

You should be aware of certain concepts that are required to understand how Remote VSS (Volume Shadow Copy Service) is used by backup services with Hyper-V over SMB configurations.

- **VSS (Volume Shadow Copy Service)**

A Microsoft technology that is used to take backup copies or snapshots of data on a specific volume at a specific point in time. VSS coordinates among data servers, backup applications, and storage management software to support the creation and management of consistent backups.

- **Remote VSS (Remote Volume Shadow Copy Service)**

A Microsoft technology that is used to take share-based backup copies of data that is in a data-consistent state at a specific point in time where the data is accessed over SMB 3.0 shares. Also known as *Volume Shadow Copy Service*.

- **Shadow copy**

A duplicate set of data contained in the share at a well-defined instant in time. Shadow copies are used to create consistent point-in-time backups of data, allowing the system or applications to continue updating data on the original volumes.

- **Shadow copy set**

A collection of one or more shadow copies, with each shadow copy corresponding to one share. The shadow copies within a shadow copy set represent all the shares that must be backed up in the same operation. The VSS client on the VSS-enabled application identifies which shadow copies to include in the set.

- **Shadow copy set automatic recovery**

The part of the backup process for remote VSS-enabled backup applications where the replica directory containing the shadow copies is made point-in-time consistent. At the start of the backup, the VSS client on the application triggers the application to take software checkpoints on the data scheduled for backup (the virtual machine files in the case of Hyper-V). The VSS client then allows the applications to continue. After the shadow copy set is created, Remote VSS makes the shadow copy set writeable and exposes the writeable copy to the applications. The application prepares the shadow copy set for backup by performing an automatic recovery using the software checkpoint taken earlier. Automatic recovery brings the shadow copies into a consistent state by unrolling the changes made to the files and directories since the checkpoint was created. Automatic recovery is an optional step for VSS-enabled backups.

- **Shadow copy ID**

A GUID that uniquely identifies a shadow copy.

- **Shadow copy set ID**

A GUID that uniquely identifies a collection of shadow copy IDs to the same server.

- **SnapManager for Hyper-V**

The software that automates and simplifies backup-and-restore operations for Microsoft Windows Server 2012 Hyper-V. SnapManager for Hyper-V uses Remote VSS with automatic recovery to back up Hyper-V

files over SMB shares.

[Key concepts about nondisruptive operations for Hyper-V and SQL Server over SMB](#)

[Share-based backups with Remote VSS](#)

Example of a directory structure used by Remote VSS

Remote VSS traverses the directory structure that stores Hyper-V virtual machine files as it creates shadow copies. It is important to understand what an appropriate directory structure is, so that you can successfully create backups of virtual machine files.

A supported directory structure for the successful creation of shadow copies conforms to the following requirements:

- Only directories and regular files are present within the directory structure that is used to store virtual machine files.

The directory structure does not contain junctions, links, or non-regular files.

- All files for a virtual machine reside within a single share.
- The directory structure that is used to store virtual machine files does not exceed the configured depth of the shadow copy directory.
- The root directory of the share contains only virtual machine files or directories.

In the following illustration, the volume named `vm_vol1` is created with a junction point at `/hyperv/vm1` on storage virtual machine (SVM) `vs1`. Subdirectories to contain the virtual machine files are created under the junction point. The virtual machine files of the Hyper-V server are accessed over `share1` that has the path `/hyperv/vm1/dir1/vmdir`. The shadow copy service creates shadow copies of all the virtual machine files that are contained within the directory structure under `share1` (up to the configured depth of the shadow copy directory).

How SnapManager for Hyper-V manages Remote VSS-based backups for Hyper-V over SMB

You can use SnapManager for Hyper-V to manage Remote VSS-based backup services. There are benefits to using SnapManager for Hyper-V managed backup service to create space efficient backup sets.

Optimizations to SnapManager for Hyper-V managed backups include the following:

- SnapDrive integration with ONTAP provides performance optimization when discovering SMB share location.

ONTAP provides SnapDrive with the name of the volume where the share resides.

- SnapManager for Hyper-V specifies the list of virtual machine files in the SMB shares that the shadow copy service needs to copy.

By providing a targeted list of virtual machine files, the shadow copy service does not need to create shadow copies of all the files in the share.

- The storage virtual machine (SVM) retains the Snapshot copies for SnapManager for Hyper-V to use for restores.

There is no backup phase. The backup is the space-efficient Snapshot copy.

SnapManager for Hyper-V provides backup and restore capabilities for HyperV over SMB using the following process:

1. Preparing for the shadow copy operation

The SnapManager for Hyper-V application's VSS client sets up the shadow copy set. The VSS client gathers information about what shares to include in the shadow copy set and provides this information to ONTAP. A set might contain one or more shadow copies, and one shadow copy corresponds to one share.

2. Creating the shadow copy set (if automatic-recovery is used)

For every share included in the shadow copy set, ONTAP creates a shadow copy and makes the shadow copy writable.

3. Exposing the shadow copy set

After ONTAP creates the shadow copies, they are exposed to SnapManager for Hyper-V so that the application's VSS writers can perform automatic recovery.

4. Automatically recovering the shadow copy set

During the shadow copy set creation, there is a period of time when active changes are occurring to the files included in the backup set. The application's VSS writers must update the shadow copies to make sure that they are in a completely consistent state prior to backup.

The way that automatic recovery is done is application specific. Remote VSS is not involved in this phase.

5. Completing and cleaning up the shadow copy set

The VSS client notifies ONTAP after it completes automatic recovery. The shadow copy set is made read-only and then is ready for backup. When using SnapManager for Hyper-V for backup, the files in a Snapshot copy become the backup; therefore, for the backup phase, a Snapshot copy is created for every volume containing shares in the backup set. After the backup is complete, the shadow copy set is removed from the CIFS server.

How ODX copy offload is used with Hyper-V and SQL Server over SMB shares

Offloaded Data Transfer (ODX), also known as *copy offload*, enables direct data transfers within or between compatible storage devices without transferring the data through the host computer. ONTAP ODX copy offload provides you with performance benefits when performing copy operations on your application server over SMB installation.

In non-ODX file transfers, the data is read from the source CIFS server and is transferred across the network to the client computer. The client computer transfers the data back over the network to the destination CIFS server. In summary, the client computer reads the data from the source and writes it to the destination. With ODX file transfers, data is copied directly from the source to the destination.

Because ODX offloaded copies are performed directly between the source and destination storage, there are significant performance benefits. The performance benefits realized include faster copy time between source and destination, reduced resource utilization (CPU, memory) on the client, and reduced network I/O bandwidth utilization.

This functionality is available on Windows Server 2012 servers. ONTAP ODX copy offload is supported on both SAN LUNs and SMB 3.0 continuously available connections.

The following use cases support using ODX copies and moves:

- Intra-volume

The source and destination files or LUNs are within the same volume.

- Inter-volume, same node, same storage virtual machine (SVM)

The source and destination files or LUNs are on different volumes that are located on the same node. The data is owned by the same SVM.

- Inter-volume, different nodes, same SVM

The source and destination files or LUNs are on different volumes that are located on different nodes. The data is owned by the same SVM.

- Inter-SVM, same node

The source and destination file or LUNs are on different volumes that are located on the same node. The data is owned by different SVMs.

- Inter-SVM, different nodes

The source and destination file or LUNs are on different volumes that are located on different nodes. The data is owned by different SVMs.

Specific use cases for ODX copy offload with Hyper-V solutions include the following:

- You can use ODX copy offload pass-through with Hyper-V to copy data within or across virtual hard disk (VHD) files or to copy data between mapped SMB shares and connected iSCSI LUNs within the same cluster.

This allows copies from guest operating systems to pass through to the underlying storage.

- When creating fixed-sized VHDs, ODX is used for initializing the disk with zeros, using a well-known zeroed token.
- ODX copy offload is used for virtual machine storage migration if the source and destination storage is on the same cluster.

 To take advantage of the use cases for ODX copy offload pass-through with Hyper-V, the guest operating system must support ODX and the guest operating system's disks must be SCSI disks backed by storage (either SMB or SAN) that supports ODX. IDE disks on the guest operating system do not support ODX pass-through.

Specific use cases for ODX copy offload with SQL Server solutions include the following:

- You can use ODX copy offload to export and import SQL Server databases between mapped SMB shares or between SMB shares and connected iSCSI LUNs within the same cluster.
- ODX copy offload is used for database exports and imports if the source and destination storage is on the same cluster.

Configuration requirements and considerations

ONTAP and licensing requirements

You need to be aware of certain ONTAP and licensing requirements when creating SQL Server or Hyper-V over SMB solutions for nondisruptive operations on SVMs.

ONTAP version requirements

- Hyper-V over SMB

ONTAP supports nondisruptive operations over SMB shares for Hyper-V running on Windows 2012 or later.

- SQL Server over SMB

ONTAP supports nondisruptive operations over SMB shares for SQL Server 2012 or later running on Windows 2012 or later.

For the latest information about supported versions of ONTAP, Windows Server, and SQL Server for nondisruptive operations over SMB shares, see the Interoperability Matrix.

[NetApp Interoperability Matrix Tool](#)

Licensing requirements

The following licenses are required:

- CIFS
- FlexClone (for Hyper-V over SMB only)

This license is required if Remote VSS is used for backups. The shadow copy service uses FlexClone to create point-in-time copies of files that are then used when creating a backup.

A FlexClone license is optional if you use a backup method that does not use Remote VSS.

Network and data LIF requirements

You need to be aware of certain network and data LIF requirements when creating SQL Server or Hyper-V over SMB configurations for nondisruptive operations).

Network protocol requirements

- IPv4 and IPv6 networks are supported.
- SMB 3.0 or later is required.

SMB 3.0 provides the functionality needed to create the continuously available SMB connections necessary to offer nondisruptive operations.

- DNS servers must contain entries that map the CIFS server name to the IP addresses assigned to the data LIFs on the storage virtual machine (SVM).

The Hyper-V or SQL Server application servers typically make multiple connections over multiple data LIFs when accessing virtual machine or database files. For proper functionality, the application servers must make these multiple SMB connections by using the CIFS server name instead of making multiple

connections to multiple unique IP addresses.

Witness also requires the use of the CIFS server's DNS name instead of individual LIF IP addresses.

Beginning with ONTAP 9.4, you can improve throughput and fault tolerance for Hyper-V and SQL server over SMB configurations by enabling SMB Multichannel. To do so, you must have multiple 1G, 10G, or larger NICs deployed on the cluster and clients.

Data LIF requirements

- The SVM hosting the application server over SMB solution must have at least one operational data LIF on every node in the cluster.

SVM data LIFs can fail over to other data ports within the cluster, including nodes that are not currently hosting data accessed by the application servers. Additionally, because the Witness node is always the SFO partner of a node to which the application server is connected, every node in the cluster is a potential Witness node.

- Data LIFs must not be configured to automatically revert.

After a takeover or giveback event, you should manually revert the data LIFs to their home ports.

- All data LIF IP addresses must have an entry in DNS and all entries must resolve to the CIFS server name.

The application servers must connect to SMB shares by using the CIFS server name. You must not configure the application servers to make connections by using the LIF IP addresses.

- If the CIFS server name is different from the SVM name, the DNS entries must resolve to the CIFS server name.

SMB server and volume requirements for Hyper-V over SMB

You need to be aware of certain SMB server and volume requirements when creating Hyper-V over SMB configurations for nondisruptive operations.

SMB server requirements

- SMB 3.0 must be enabled.

This is enabled by default.

- The default UNIX user CIFS server option must be configured with a valid UNIX user account.

The application servers use the machine account when creating an SMB connection. Because all SMB access requires that the Windows user successfully map to a UNIX user account or to the default UNIX user account, ONTAP must be able to map the application server's machine account to the default UNIX user account.

- Automatic node referrals must be disabled (this functionality is disabled by default).

If you want to use automatic node referrals for access to data other than Hyper-V machine files, you must create a separate SVM for that data.

- Both Kerberos and NTLM authentication must be allowed in the domain to which the SMB server belongs.

ONTAP does not advertise the Kerberos service for Remote VSS; therefore, the domain should be set to permit NTLM.

- Shadow copy functionality must be enabled.

This functionality is enabled by default.

- The Windows domain account that the shadow copy service uses when creating shadow copies must be a member of the SMB server local BUILTIN\Administrators or BUILTIN\Backup Operators group.

Volume requirements

- Volumes used to store virtual machine files must be created as NTFS security-style volumes.

To provide NDOs for application servers using continuously available SMB connections, the volume containing the share must be an NTFS volume. Moreover, it must always have been an NTFS volume. You cannot change a mixed security-style volume or UNIX security-style volume to an NTFS security-style volume and directly use it for NDOs over SMB shares. If you change a mixed security-style volume to an NTFS security style volume and intend to use it for NDOs over SMB shares, you must manually place an ACL at the top of the volume and propagate that ACL to all contained files and folders. Otherwise, virtual machine migrations or database file exports and imports where files are moved to another volume can fail if either the source or the destination volumes were initially created as mixed or UNIX security-style volumes and later changed to NTFS security style.

- For shadow copy operations to succeed, you must have enough available space on the volume.

The available space must be at least as large as the combined space used by all files, directories, and subdirectories contained within the shares included in the shadow copy backup set. This requirement only applies to shadow copies with auto-recovery.

SMB server and volume requirements for SQL Server over SMB

You need to be aware of certain SMB server and volume requirements when creating SQL Server over SMB configurations for nondisruptive operations.

SMB server requirements

- SMB 3.0 must be enabled.

This is enabled by default.

- The default UNIX user CIFS server option must be configured with a valid UNIX user account.

The application servers use the machine account when creating an SMB connection. Because all SMB access requires that the Windows user successfully map to a UNIX user account or to the default UNIX user account, ONTAP must be able to map the application server's machine account to the default UNIX user account.

Additionally, SQL Server uses a domain user as the SQL Server service account. The service account must also map to the default UNIX user.

- Automatic node referrals must be disabled (this functionality is disabled by default).

If you want to use automatic node referrals for access to data other than SQL server database files, you must create a separate SVM for that data.

- The Windows user account used for installing SQL Server on ONTAP must be assigned the SeSecurityPrivilege privilege.

This privilege is assigned to the SMB server local BUILTIN\Administrators group.

Volume requirements

- Volumes used to store virtual machine files must be created as NTFS security-style volumes.

To provide NDOs for application servers using continuously available SMB connections, the volume containing the share must be an NTFS volume. Moreover, it must always have been an NTFS volume. You cannot change a mixed security-style volume or UNIX security-style volume to an NTFS security-style volume and directly use it for NDOs over SMB shares. If you change a mixed security-style volume to an NTFS security style volume and intend to use it for NDOs over SMB shares, you must manually place an ACL at the top of the volume and propagate that ACL to all contained files and folders. Otherwise, virtual machine migrations or database file exports and imports where files are moved to another volume can fail if either the source or the destination volumes were initially created as mixed or UNIX security-style volumes and later changed to NTFS security style.

- Although the volume containing the database files can contain junctions, SQL Server does not cross junctions when creating the database directory structure.
- For SnapCenter Plug-in for Microsoft SQL Server backup operations to succeed, you must have enough available space on the volume.

The volume on which the SQL Server database files reside must be large enough to hold the database directory structure and all contained files residing within the share.

Continuously available share requirements and considerations for Hyper-V over SMB

You need to be aware of certain requirements and considerations when configuring continuously available shares for Hyper-V over SMB configurations that support nondisruptive operations.

Share requirements

- Shares used by the application servers must be configured with the continuously available property set.

Application servers that connect to continuously available shares receive persistent handles that allow them to reconnect nondisruptively to SMB shares and reclaim file locks after disruptive events, such as takeover, giveback, and aggregate relocation.

- If you want to use Remote VSS-enabled backup services, you cannot put Hyper-V files into shares that contain junctions.

In the auto-recovery case, the shadow copy creation fails if a junction is encountered while traversing the

share. In the non auto-recovery case, the shadow copy creation does not fail, but the junction does not point to anything.

- If you want to use Remote VSS-enabled backup services with auto-recovery, you cannot put Hyper-V files into shares that contain the following:
 - Symlinks, hardlinks, or widelinks
 - Non-regular files

The shadow copy creation fails if there are any links or non-regular files in the share to shadow copy. This requirement only applies to shadow copies with auto-recovery.

- For shadow copy operations to succeed, you must have enough available space on the volume (for Hyper-V over SMB only).

The available space must be at least as large as the combined space used by all files, directories, and subdirectories contained within the shares included in the shadow copy backup set. This requirement only applies to shadow copies with auto-recovery.

- The following share properties must not be set on continuously available shares used by the application servers:
 - Home directory
 - Attribute caching
 - BranchCache

Considerations

- Quotas are supported on continuously available shares.
- The following functionality is not supported for Hyper-V over SMB configurations:
 - Auditing
 - FPolicy
- Virus scanning is not performed on SMB shares with the `continuously-availability` parameter set to Yes.

Continuously available share requirements and considerations for SQL Server over SMB

You need to be aware of certain requirements and considerations when configuring continuously available shares for SQL Server over SMB configurations that support nondisruptive operations.

Share requirements

- Volumes used to store virtual machine files must be created as NTFS security-style volumes.

To provide nondisruptive operations for application servers using continuously available SMB connections, the volume containing the share must be an NTFS volume. Moreover, it must always have been an NTFS volume. You cannot change a mixed security-style volume or UNIX security-style volume to an NTFS security-style volume and directly use it for nondisruptive operations over SMB shares. If you change a mixed security-style volume to an NTFS security style volume and intend to use it for nondisruptive operations over SMB shares, you must manually place an ACL at the top of the volume and propagate that ACL to all contained files and folders. Otherwise, virtual machine migrations or database file exports and

imports where files are moved to another volume can fail if either the source or the destination volumes were initially created as mixed or UNIX security-style volumes and later changed to NTFS security style.

- Shares used by the application servers must be configured with the continuously available property set.

Application servers that connect to continuously available shares receive persistent handles that allow them to reconnect nondisruptively to SMB shares and reclaim file locks after disruptive events, such as takeover, giveback, and aggregate relocation.

- Although the volume containing the database files can contain junctions, SQL Server does not cross junctions when creating the database directory structure.
- For SnapCenter Plug-in for Microsoft SQL Server operations to succeed, you must have enough available space on the volume.

The volume on which the SQL Server database files reside must be large enough to hold the database directory structure and all contained files residing within the share.

- The following share properties must not be set on continuously available shares used by the application servers:
 - Home directory
 - Attribute caching
 - BranchCache

Share considerations

- Quotas are supported on continuously available shares.
- The following functionality is not supported for SQL Server over SMB configurations:
 - Auditing
 - FPolicy
- Virus scanning is not performed on SMB shares with the continuously-availability share property set.

Remote VSS considerations for Hyper-V over SMB configurations

You need to be aware of certain considerations when using Remote VSS-enabled backup solutions for Hyper-V over SMB configurations.

General Remote VSS considerations

- A maximum of 64 shares can be configured per Microsoft application server.

The shadow copy operation fails if there are more than 64 shares in a shadow copy set. This is a Microsoft requirement.

- Only one active shadow copy set per CIFS server is allowed.

A shadow copy operation will fail if there is an ongoing shadow copy operation on the same CIFS server. This is a Microsoft requirement.

- No junctions are allowed within the directory structure on which Remote VSS creates a shadow copy.

- In the automatic recovery case, the shadow copy creation will fail if a junction is encountered while traversing the share.
- In the nonautomatic recovery case, the shadow copy creation does not fail, but the junction does not point to anything.

Remote VSS considerations that apply only for shadow copies with automatic recovery

Certain limits apply only for shadow copies with automatic recovery.

- A maximum directory depth of five subdirectories is allowed for shadow copy creation.

This is the directory depth over which the shadow copy service creates a shadow copy backup set. Shadow copy creation fails if directories containing virtual machine file are nested deeper than five levels. This is intended to limit the directory traversal when cloning the share. The maximum directory depth can be changed by using a CIFS server option.

- Amount of available space on the volume must be adequate.

The available space must be at least as large as the combined space used by all files, directories, and subdirectories contained within the shares included in the shadow copy backup set.

- No links or non-regular files are allowed within the directory structure on which Remote VSS creates a shadow copy.

The shadow copy creation fails if there are any links or non-regular files in the share to the shadow copy. The clone process does not support them.

- No NFSv4 ACLs are allowed on directories.

Although shadow copy creation retains NFSv4 ACLs on files, the NFSv4 ACLs on directories are lost.

- A maximum of 60 seconds is allowed to create a shadow copy set.

Microsoft specifications allow a maximum of 60 seconds to create the shadow copy set. If the VSS client cannot create the shadow copy set within this time, the shadow copy operation fails; therefore, this limits the number of files in a shadow copy set. The actual number of files or virtual machines that can be included in a backup set varies; that number is dependent on many factors, and must be determined for each customer environment.

ODX copy offload requirements for SQL Server and Hyper-V over SMB

ODX copy offload must be enabled if you want to migrate virtual machine files or export and import database files directly from source to the destination storage location without sending data through the application servers. There are certain requirements that you must understand about using ODX copy offload with SQL Server and Hyper-V over SMB solutions.

Using ODX copy offload provides a significant performance benefit. This CIFS server option is enabled by default.

- SMB 3.0 must be enabled to use ODX copy offload.
- Source volumes must be a minimum of 1.25 GB.

- Deduplication must be enabled on volumes used with copy offload.
- If you use compressed volumes, the compression type must be adaptive and only compression group size 8K is supported.

Secondary compression type is not supported

- To use ODX copy offload to migrate Hyper-V guests within and between disks, the Hyper-V servers must be configured to use SCSI disks.

The default is to configure IDE disks, but ODX copy offload does not work when guests are migrated if disks are created using IDE disks.

Recommendations for SQL Server and Hyper-V over SMB configurations

To be sure that your SQL Server and Hyper-V over SMB configurations are robust and operational, you need to be familiar with recommended best practices when configuring the solutions.

General recommendations

- Separate application server files from general user data.

If possible, devote an entire storage virtual machine (SVM) and its storage for the application server's data.

- For best performance, do not enable SMB signing on SVMs that are used to store the application server's data.
- For best performance and improved fault tolerance, enable SMB Multichannel to provide multiple connections between ONTAP and clients in a single SMB session.
- Do not create continuously available shares on any shares other than those used in the Hyper-V or SQL Server over SMB configuration.
- Disable change notify on shares used for continuous availability.
- Do not perform a volume move at the same time as aggregate relocation (ARL) because ARL has phases that pause some operations.
- For Hyper-V over SMB solutions, use in-guest iSCSI drives when creating clustered virtual machines. Shared .VHDX files are not supported for Hyper-V over SMB in ONTAP SMB shares.

Plan the Hyper-V or SQL Server over SMB configuration

Complete the volume configuration worksheet

The worksheet provides an easy way to record the values that you need when creating volumes for SQL Server and Hyper-V over SMB configurations.

For each volume, you must specify the following information:

- storage virtual machine (SVM) name

The SVM name is the same for all volumes.

- Volume name

- Aggregate name

You can create volumes on aggregates located on any node in the cluster.

- Size
- Junction path

You should keep the following in mind when creating volumes used to store application server data:

- If the root volume does not have NTFS security style, you must specify the security style as NTFS when you create the volume.

By default, volumes inherit the security style of the SVM root volume.

- Volumes should be configured with the default volume space guarantee.
- You can optionally configure the autosize space management setting.
- You should set the option that determines the Snapshot copy space reserve to 0.
- The Snapshot policy applied to the volume must be disabled.

If the SVM Snapshot policy is disabled, then you do not need to specify a Snapshot policy for the volumes. The volumes inherit the Snapshot policy for the SVM. If the Snapshot policy for the SVM is not disabled and is configured to create Snapshot copies, you must specify a Snapshot policy at the volume level, and that policy must be disabled. Shadow copy service-enabled backups and SQL Server backups manage Snapshot copy creation and deletion.

- You cannot configure load-sharing mirrors for the volumes.

Junction paths on which you plan to create shares that the application servers use should be chosen so that there are no junctioned volumes below the share entry point.

For example, if you want to store virtual machine files on four volumes named “vol1”, “vol2”, “vol3”, and “vol4”, you can create the namespace shown in the example. You can then create shares for the application servers at the following paths: /data1/vol1, /data1/vol2, /data2/vol3, and /data2/vol4.

Vserver	Volume	Junction Active	Junction Path	Junction Path Source
vs1	data1	true	/data1	RW_volume
vs1	vol1	true	/data1/vol1	RW_volume
vs1	vol2	true	/data1/vol2	RW_volume
vs1	data2	true	/data2	RW_volume
vs1	vol3	true	/data2/vol3	RW_volume
vs1	vol4	true	/data2/vol4	RW_volume

Types of information	Values
Volume 1: Volume name, aggregate, size, junction path	

Types of information	Values
<i>Volume 2: Volume name, aggregate, size, junction path</i>	
<i>Volume 3: Volume name, aggregate, size, junction path</i>	
<i>Volume 4: Volume name, aggregate, size, junction path</i>	
<i>Volume 5: Volume name, aggregate, size, junction path</i>	
<i>Volume 6: Volume name, aggregate, size, junction path</i>	
<i>Additional volumes: Volume name, aggregate, size, junction path</i>	

Complete the SMB share configuration worksheet

Use this worksheet to record the values that you need when creating continuously available SMB shares for SQL Server and Hyper-V over SMB configurations.

Information about SMB shares properties and configuration settings

For each share, you must specify the following information:

- storage virtual machine (SVM) name

The SVM name is the same for all shares

- Share name
- Path
- Share properties

You must configure the following two share properties:

- oplocks
- continuously-available

The following share properties must not be set:

- homedirectory attributecache
- branchcache
- access-based-enumeration

With change notify disabled, Windows 2012 Server does not refresh the Explorer window, which causes an inconsistent view of directory contents.

- Symlinks must be disabled (the value for the `-symlink-properties` parameter must be null [""]).

Information about share paths

If you are using Remote VSS to back up Hyper-V files, the choice of share paths to use when making SMB connections from the Hyper-V servers to the storage locations where the virtual machine files are stored is important. Although shares can be created at any point in the namespace, paths for shares that the Hyper-V servers use should not contain junctioned volumes. Shadow copy operations cannot be performed on share paths that contain junction points.

SQL Server cannot cross junctions when creating the database directory structure. You should not create share paths for SQL server that contain junction points.

For example, given the namespace shown, if you want to store virtual machine files or database files on volumes “vol1”, “vol2”, “vol3”, and “vol4”, you should create shares for the application servers at the following paths: /data1/vol1, /data1/vol2, /data2/vol3, and /data2/vol4.

Vserver	Volume	Junction		Path Source
		Active	Junction Path	
vs1	data1	true	/data1	RW_volume
vs1	vol1	true	/data1/vol1	RW_volume
vs1	vol2	true	/data1/vol2	RW_volume
vs1	data2	true	/data2	RW_volume
vs1	vol3	true	/data2/vol3	RW_volume
vs1	vol4	true	/data2/vol4	RW_volume

Although you can create shares on the /data1 and /data2 paths for administrative management, you must not configure the application servers to use those shares to store data.

Planning worksheet

<i>Additional volumes: SMB share names and paths</i>	

Create ONTAP configurations for nondisruptive operations with Hyper-V and SQL Server over SMB

Create ONTAP configurations for nondisruptive operations with Hyper-V and SQL Server over SMB overview

There are several ONTAP configuration steps you must perform to prepare for Hyper-V and SQL Server installations that provides nondisruptive operations over SMB.

Before you create the ONTAP configuration for nondisruptive operations with Hyper-V and SQL Server over SMB, the following tasks must be completed:

- Time services must be set up on the cluster.
- Networking must be set up for the SVM.
- The SVM must be created.
- Data LIF interfaces must be configured on the SVM.
- DNS must be configured on the SVM.
- Desired names services must be set up for the SVM.
- The SMB server must be created.

[Configuration requirements and considerations](#)

Verify that both Kerberos and NTLMv2 authentication are permitted (Hyper-V over SMB shares)

Nondisruptive operations for Hyper-V over SMB require that the CIFS server on a data SVM and the Hyper-V server permit both Kerberos and NTLMv2 authentication. You must verify settings on both the CIFS server and the Hyper-V servers that control what authentication methods are permitted.

About this task

Kerberos authentication is required when making a continuously available share connection. Part of the Remote VSS process uses NTLMv2 authentication. Therefore, connections using both authentication methods must be supported for Hyper-V over SMB configurations.

The following settings must be configured to allow both Kerberos and NTLMv2 authentication:

- Export policies for SMB must be disabled on the storage virtual machine (SVM).

Both Kerberos and NTLMv2 authentication are always enabled on SVMs, but export policies can be used to restrict access based on authentication method.

Export policies for SMB are optional and are disabled by default. If export policies are disabled, both Kerberos and NTLMv2 authentication are allowed on a CIFS server by default.

- The domain to which the CIFS server and Hyper-V servers belong must permit both Kerberos and NTLMv2 authentication.

Kerberos authentication is enabled by default on Active Directory domains. However, NTLMv2 authentication can be disallowed, either using Security Policy settings or Group Policies.

Steps

1. Perform the following to verify that export policies are disabled on the SVM:

- a. Set the privilege level to advanced:

```
set -privilege advanced
```

- b. Verify that the `-is-exportpolicy-enabled` CIFS server option is set to `false`:

```
vserver cifs options show -vserver vserver_name -fields vserver,is-exportpolicy-enabled
```

- c. Return to the admin privilege level:

```
set -privilege admin
```

2. If export policies for SMB are not disabled, disable them:

```
vserver cifs options modify -vserver vserver_name -is-exportpolicy-enabled false
```

3. Verify that both NTLMv2 and Kerberos authentication are allowed in the domain.

For information about determining what authentication methods are allowed in the domain, see the Microsoft TechNet Library.

4. If the domain does not permit NTMLv2 authentication, enable NTMLv2 authentication by using one of the methods described in Microsoft documentation.

Example

The following commands verify that export policies for SMB are disabled on SVM vs1:

```

cluster1::> set -privilege advanced
Warning: These advanced commands are potentially dangerous; use them
only when directed to do so by technical support personnel.
Do you wish to continue? (y or n): y

cluster1::*> vserver cifs options show -vserver vs1 -fields vserver,is-
exportpolicy-enabled

vserver  is-exportpolicy-enabled
-----
vs1      false

cluster1::*> set -privilege admin

```

Verify that domain accounts map to the default UNIX user

Hyper-V and SQL Server use domain accounts to create SMB connections to continuously available shares. To successfully create the connection, the computer account must successfully map to a UNIX user. The most convenient way to accomplish this is to map the computer account to the default UNIX user.

About this task

Hyper-V and SQL Server use the domain computer accounts to create SMB connections. In addition, SQL Server uses a domain user account as the service account that also makes SMB connections.

When you create a storage virtual machine (SVM), ONTAP automatically creates the default user named “pcuser” (with a UID of 65534) and the group named “pcuser” (with a GID of 65534), and adds the default user to the “pcuser” group. If you are configuring a Hyper-V over SMB solution on anSVM that existed prior to upgrading the cluster to Data ONTAP 8.2, the default user and group might not exist. If they do not, you must create them before configuring the CIFS server’s default UNIX user.

Steps

1. Determine whether there is a default UNIX user:

```
vserver cifs options show -vserver vserver_name
```

2. If the default user option is not set, determine whether there is a UNIX user that can be designated as the default UNIX user:

```
vserver services unix-user show -vserver vserver_name
```

3. If the default user option is not set and there is not a UNIX user that can be designated as the default UNIX user, create the default UNIX user and the default group, and add the default user to the group.

Generally, the default user is given the user name “pcuser” and must be assigned the UID of 65534. The default group is generally given the group name “pcuser”. The GID assigned to the group must be 65534.

- a. Create the default group:

+

```
vserver services unix-group create -vserver vserver_name -name pcuser -id 65534
```

- b. Create the default user and add the default user to the default group:

```
+  
vserver services unix-user create -vserver vserver_name -user pcuser -id 65534 -primary-gid 65534
```

- c. Verify that the default user and default group are configured correctly:

```
+  
vserver services unix-user show -vserver vserver_name  
+  
vserver services unix-group show -vserver vserver_name -members
```

4. If the CIFS server's default user is not configured, perform the following:

- a. Configure the default user:

```
vserver cifs options modify -vserver *vserver_name -default-unix-user pcuser*
```

- b. Verify that the default UNIX user is configured correctly:

```
vserver cifs options show -vserver vserver_name
```

5. To verify that the application server's computer account correctly maps to the default user, map a drive to a share residing on the SVM and confirm the Windows user to UNIX user mapping by using the vserver cifs session show command.

For more information about using this command, see the man pages.

Example

The following commands determine that the CIFS server's default user is not set, but determines that the "pcuser" user and "pcuser" group exist. The "pcuser" user is assigned as the CIFS server's default user on SVM vs1.

```
cluster1::> vserver cifs options show
```

```
Vserver: vs1
```

```
Client Session Timeout : 900  
Default Unix Group     : -  
Default Unix User      : -  
Guest Unix User        : -  
Read Grants Exec       : disabled  
Read Only Delete       : disabled  
WINS Servers          : -
```

```
cluster1::> vserver services unix-user show
```

User	User	Group	Full
------	------	-------	------

```

Vserver      Name          ID      ID      Name
-----      -----          -----      -----
vs1         nobody        65535   65535   -
vs1         pcuser        65534   65534   -
vs1         root          0       1       -

cluster1::> vserver services unix-group show -members
Vserver      Name          ID
vs1         daemon        1
    Users: -
vs1         nobody        65535
    Users: -
vs1         pcuser        65534
    Users: -
vs1         root          0
    Users: -

cluster1::> vserver cifs options modify -vserver vs1 -default-unix-user
pcuser

cluster1::> vserver cifs options show

Vserver: vs1

Client Session Timeout : 900
Default Unix Group     : -
Default Unix User       : pcuser
Guest Unix User         : -
Read Grants Exec        : disabled
Read Only Delete        : disabled
WINS Servers            : -

```

Verify that the security style of the SVM root volume is set to NTFS

To ensure that nondisruptive operations for Hyper-V and SQL Server over SMB are successful, volumes must be created with NTFS security style. Since the root volume's security style is applied by default to volumes created on the storage virtual machine (SVM), the security style of the root volume should be set to NTFS.

About this task

- You can specify the root volume security style at the time you create the SVM.
- If the SVM is not created with the root volume set to NTFS security style, you can change the security style later by using the `volume modify` command.

Steps

1. Determine the current security style of the SVM root volume:

```
volume show -vserver vserver_name -fields vserver,volume,security-style
```

2. If the root volume is not an NTFS security-style volume, change the security style to NTFS:

```
volume modify -vserver vserver_name -volume root_volume_name -security-style ntfs
```

3. Verify that the SVM root volume is set to NTFS security style:

```
volume show -vserver vserver_name -fields vserver,volume,security-style
```

Example

The following commands verify that the root volume security style is NTFS on SVM vs1:

```
cluster1::> volume show -vserver vs1 -fields vserver,volume,security-style  
vserver    volume      security-style  
-----  
vs1        vs1_root    unix  
  
cluster1::> volume modify -vserver vs1 -volume vs1_root -security-style  
ntfs  
  
cluster1::> volume show -vserver vs1 -fields vserver,volume,security-style  
vserver    volume      security-style  
-----  
vs1        vs1_root    ntfs
```

Verify that required CIFS server options are configured

You must verify that the required CIFS server options are enabled and configured according to requirements for nondisruptive operations for Hyper-V and SQL Server over SMB.

About this task

- SMB 2.x and SMB 3.0 must be enabled.
- ODX copy offload must be enabled to use performance enhancing copy offload.
- VSS Shadow Copy services must be enabled if the Hyper-V over SMB solution uses Remote VSS-enabled backup services (Hyper-V only).

Steps

1. Verify that the required CIFS server options are enabled on the storage virtual machine (SVM):

- a. Set the privilege level to advanced:

```
set -privilege advanced
```

- b. Enter the following command:

```
vserver cifs options show -vserver vserver_name
```

The following options should be set to true:

- -smb2-enabled
- -smb3-enabled
- -copy-offload-enabled
- -shadowcopy-enabled (Hyper-V only)

2. If any of the options are not set to true, perform the following:

- a. Set them to true by using the vserver cifs options modify command.
- b. Verify that the options are set to true by using the vserver cifs options show command.

3. Return to the admin privilege level:

```
set -privilege admin
```

Example

The following commands verify that the required options for the Hyper-V over SMB configuration are enabled on SVM vs1. In the example, ODX copy offload must be enabled to meet the option requirements.

```
cluster1::> set -privilege advanced
Warning: These advanced commands are potentially dangerous; use them
only when directed to do so by technical support personnel.
Do you wish to continue? (y or n): y

cluster1::*> vserver cifs options show -vserver vs1 -fields smb2-
enabled,smb3-enabled,copy-offload-enabled,shadowcopy-enabled
vserver smb2-enabled smb3-enabled copy-offload-enabled shadowcopy-enabled
-----
vs1      true        true        false        true

cluster-1::*> vserver cifs options modify -vserver vs1 -copy-offload-
-enabled true

cluster-1::*> vserver cifs options show -vserver vs1 -fields copy-offload-
enabled
vserver  copy-offload-enabled
-----
vs1      true

cluster1::*> set -privilege admin
```

Configure SMB Multichannel for performance and redundancy

Beginning with ONTAP 9.4, you can configure SMB Multichannel to provide multiple

connections between ONTAP and clients in a single SMB session. Doing so improves throughput and fault tolerance for Hyper-V and SQL server over SMB configurations.

What you'll need

You can use SMB Multichannel functionality only when clients negotiate at SMB 3.0 or later versions. SMB 3.0 and later is enabled on the ONTAP SMB server by default.

About this task

SMB clients automatically detect and use multiple network connections if a proper configuration is identified on the ONTAP cluster.

The number of simultaneous connections in an SMB session depends on the NICs you have deployed:

- **1G NICs on client and ONTAP cluster**

The client establishes one connection per NIC and binds the session to all connections.

- **10G and larger capacity NICs on client and ONTAP cluster**

The client establishes up to four connections per NIC and binds the session to all connections. The client can establish connections on multiple 10G and larger capacity NICs.

You can also modify the following parameters (advanced privilege):

- **-max-connections-per-session**

The maximum number of connections allowed per Multichannel session. The default is 32 connections.

If you want to enable more connections than the default, you must make comparable adjustments to the client configuration, which also has a default of 32 connections.

- **-max-lifs-per-session**

The maximum number of network interfaces advertised per Multichannel session. The default is 256 network interfaces.

Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Enable SMB Multichannel on the SMB server:

```
vserver cifs options modify -vserver vserver_name -is-multichannel-enabled true
```

3. Verify that ONTAP is reporting SMB Multichannel sessions:

```
vserver cifs session show options
```

4. Return to the admin privilege level:

```
set -privilege admin
```

Example

The following example displays information about all SMB sessions, showing multiple connections for a single session:

```
cluster1::> vserver cifs session show
Node:      node1
Vserver:   vs1
Connection Session                                Open
Idle
IDs        ID       Workstation      Windows User      Files
Time
-----
-----
138683,
138684,
138685      1       10.1.1.1        DOMAIN\          0
4s
                                         Administrator
```

The following example displays detailed information about an SMB session with session-id 1:

```
cluster1::> vserver cifs session show -session-id 1 -instance

Vserver: vs1
          Node: node1
          Session ID: 1
          Connection IDs: 138683,138684,138685
          Connection Count: 3
          Incoming Data LIF IP Address: 192.1.1.1
          Workstation IP Address: 10.1.1.1
          Authentication Mechanism: NTLMv1
          User Authenticated as: domain-user
          Windows User: DOMAIN\administrator
          UNIX User: root
          Open Shares: 2
          Open Files: 5
          Open Other: 0
          Connected Time: 5s
          Idle Time: 5s
          Protocol Version: SMB3
          Continuously Available: No
          Is Session Signed: false
          NetBIOS Name: -
```

Create NTFS data volumes

You must create NTFS data volumes on the storage virtual machine (SVM) before you can configure continuously available shares for use with Hyper-V or SQL Server over SMB application servers. Use the volume configuration worksheet to create your data volumes.

About this task

There are optional parameters that you can use to customize a data volume. For more information about customizing volumes, see the [xref:/smb-hyper-v-sql/Logical storage management](#).

As you create your data volumes, you should not create junction points within a volume that contains the following:

- Hyper-V files for which ONTAP makes shadow copies
- SQL Server database files that are backed up using SQL Server

If you inadvertently create a volume that uses mixed or UNIX security style, you cannot change the volume to an NTFS security style volume and then directly use it to create continuously available shares for nondisruptive operations. Nondisruptive operations for Hyper-V and SQL Server over SMB do not work correctly unless the volumes used in the configuration are created as NTFS security-style volumes. You must either delete the volume and re-create the volume with NTFS security style, or you can map the volume on a Windows host and apply an ACL at the top of the volume and propagate the ACL to all files and folders in the volume.

Steps

1. Create the data volume by entering the appropriate command:

If you want to create a volume in an SVM where the root volume security style is...	Enter the command...
NTFS	<pre>volume create -vserver vserver_name -volume volume_name -aggregate aggregate_name -size integer[KB MB GB TB PB] -junction-path path</pre>
Not NTFS	<pre>volume create -vserver vserver_name -volume volume_name -aggregate aggregate_name -size integer[KB MB GB TB PB]- security-style ntfs -junction-path path</pre>

2. Verify that the volume configuration is correct:

```
volume show -vserver vserver_name -volume volume_name
```

Create continuously available SMB shares

After you create your data volumes, you can create the continuously available shares that the application servers use to access Hyper-V virtual machine and configuration files and

SQL Server database files. You should use the share configuration worksheet as you create the SMB shares.

Steps

1. Display information about the existing data volumes and their junction paths:

```
volume show -vserver vserver_name -junction
```

2. Create a continuously available SMB share:

```
vserver cifs share create -vserver vserver_name -share-name share_name -path path -share-properties oplocks,continuously-available -symlink "" [-comment text]
```

- You can optionally add a comment to the share configuration.
- By default, the offline files share property is configured on the share and is set to manual.
- ONTAP creates the share with the Windows default share permission of Everyone / Full Control.

3. Repeat the previous step for all shares in the share configuration worksheet.
4. Verify that your configuration is correct by using the `vserver cifs share show` command.
5. Configure NTFS file permissions on the continuously available shares by mapping a drive to each share, and configuring file permissions by using the **Windows Properties** window.

Example

The following commands create a continuously available share named “data2” on storage virtual machine (SVM, formerly known as Vserver) vs1. Symlinks are disabled by setting the `-symlink` parameter to “”:

```

cluster1::> volume show -vserver vs1 -junction
                Junction                                Junction
Vserver    Volume     Active   Junction Path      Path Source
-----
vs1        data       true     /data           RW_volume
vs1        data1      true     /data/data1    RW_volume
vs1        data2      true     /data/data2    RW_volume
vs1        vs1_root   -       /                  -
                                                              

cluster1::> vserver cifs share create -vserver vs1 -share-name data2 -path
/data/data2 -share-properties oplocks,continuously-available -symlink ""

cluster1::> vserver cifs share show -vserver vs1 -share-name data2

          Vserver: vs1
          Share: data2
          CIFS Server NetBIOS Name: VS1
          Path: /data/data2
          Share Properties: oplocks
                           continuously-available
          Symlink Properties: -
          File Mode Creation Mask: -
          Directory Mode Creation Mask: -
          Share Comment: -
          Share ACL: Everyone / Full Control
          File Attribute Cache Lifetime: -
          Volume Name: -
          Offline Files: manual
          Vscan File-Operations Profile: standard

```

Add the SeSecurityPrivilege privilege to the user account (for SQL Server or SMB shares)

The domain user account used for installing the SQL server must be assigned the “SeSecurityPrivilege” privilege to perform certain actions on the CIFS server that require privileges not assigned by default to domain users.

What you'll need

The domain account used for installing the SQL Server must already exist.

About this task

When adding the privilege to the SQL Server installer's account, ONTAP might validate the account by contacting the domain controller. The command might fail if ONTAP cannot contact the domain controller.

Steps

1. Add the “SeSecurityPrivilege” privilege:

```
vserver cifs users-and-groups privilege add-privilege -vserver vserver_name  
-user-or-group-name account_name -privileges SeSecurityPrivilege
```

The value for the `-user-or-group-name` parameter is the name of the domain user account used for installing the SQL Server.

2. Verify that the privilege is applied to the account:

```
vserver cifs users-and-groups privilege show -vserver vserver_name -user-or-  
group-name account_name
```

Example

The following command adds the “SeSecurityPrivilege” privilege to the SQL Server installer’s account in the EXAMPLE domain for storage virtual machine (SVM) vs1:

```
cluster1::> vserver cifs users-and-groups privilege add-privilege -vserver  
vs1 -user-or-group-name EXAMPLE\SQLinstaller -privileges  
SeSecurityPrivilege

cluster1::> vserver cifs users-and-groups privilege show -vserver vs1
Vserver      User or Group Name          Privileges
-----      -----
vs1          EXAMPLE\SQLinstaller        SeSecurityPrivilege
```

Configure the VSS shadow copy directory depth (for Hyper-V over SMB shares)

Optionally, you can configure the maximum depth of directories within SMB shares on which to create shadow copies. This parameter is useful if you want to manually control the maximum level of subdirectories on which ONTAP should create shadow copies.

What you'll need

The VSS shadow copy feature must be enabled.

About this task

The default is to create shadow copies for a maximum of five subdirectories. If the value is set to 0, ONTAP creates shadow copies for all subdirectories.

 Although you can specify that the shadow copy set directory depth include more than five subdirectories or all subdirectories, there is a Microsoft requirement that shadow copy set creation must be completed within 60 seconds. Shadow copy set creation fails if it cannot be completed within this time. The shadow copy directory depth you choose must not cause the creation time to exceed the time limit.

Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Set the VSS shadow copy directory depth to the desired level:

```
vserver cifs options modify -vserver vserver_name -shadowcopy-dir-depth integer
```

```
vserver cifs options modify -vserver vs1 -shadowcopy-dir-depth 6
```

3. Return to the admin privilege level:

```
set -privilege admin
```

Manage Hyper-V and SQL Server over SMB configurations

Configure existing shares for continuous availability

You can modify existing shares to become continuously available shares that the Hyper-V and SQL Server application servers use to nondisruptively access Hyper-V virtual machine and configuration files and SQL Server database files.

About this task

You cannot use an existing share as a continuously available share for nondisruptive operations with application servers over SMB if the share has the following characteristics:

- If the homedirectory share property is set on that share
- If the share contains enabled symlinks or widelinks
- If the share contains junctioned volumes below the root of the share

You must verify that the two following share parameters are set correctly:

- The -offline-files parameter is set to either manual (the default) or none.
- Symlinks must be disabled.

The following share properties must be configured:

- continuously-available
- oplocks

The following share properties must not be set. If they are present in the list of current share properties, they need to be removed from the continuously available share:

- attributecache
- branchcache

Steps

1. Display the current share parameter settings and the current list of configured share properties:

```
vserver cifs share show -vserver vserver_name -share-name share_name
```

2. If necessary, modify the share parameters to disable symlinks and set offline files to manual by using the

```
vserver cifs share properties modify command.
```

You can disable symlinks by setting the value of the `-symlink` parameter to "".

- You can disable symlinks by setting the value of the `-symlink` parameter to "".
- You can set the `-offline-files` parameter to the correct setting by specifying `manual`.

3. Add the `continuously-available` share property, and, if needed, the `oplocks` share property:

```
vserver cifs share properties add -vserver vserver_name -share-name share_name  
-share-properties continuously-available[,oplock]
```

If the `oplocks` share property is not already set, you must add it along with the `continuously-available` share property.

4. Remove any share properties that are not supported on continuously available shares:

```
vserver cifs share properties remove -vserver vserver_name -share-name  
share_name -share-properties properties[,...]
```

You can remove one or more share properties by specifying the share properties with a comma-delimited list.

5. Verify that the `-symlink` and `-offline-files` parameters are set correctly:

```
vserver cifs share show -vserver vserver_name -share-name share_name -fields  
symlink-properties,offline-files
```

6. Verify that the list of configured share properties is correct:

```
vserver cifs shares properties show -vserver vserver_name -share-name  
share_name
```

Examples

The following example shows how to configure an existing share named "share1" on storage virtual machine (SVM) vs1 for NDOs with an application server over SMB:

- Symlinks are disabled on the share by setting the `-symlink` parameter to "".
- The `-offline-file` parameter is modified and set to `manual`.
- The `continuously-available` share property is added to the share.
- The `oplocks` share property is already in the list of share properties; therefore, it does not need to be added.
- The `attributecache` share property is removed from the share.
- The `browsable` share property is optional for a continuously available share used for NDOs with application servers over SMB and is retained as one of the share properties.

```

cluster1::> vserver cifs share show -vserver vs1 -share-name share1

          Vserver: vs1
          Share: share1
CIFS Server NetBIOS Name: vs1
          Path: /data
Share Properties: oplocks
                  browsable
                  attributecache
Symlink Properties: enable
File Mode Creation Mask: -
Directory Mode Creation Mask: -
Share Comment: -
          Share ACL: Everyone / Full Control
File Attribute Cache Lifetime: 10s
          Volume Name: data
          Offline Files: documents
Vscan File-Operations Profile: standard

cluster1::> vserver cifs share modify -vserver vs1 -share-name share1
-offline-file manual -symlink ""

cluster1::> vserver cifs share properties add -vserver vs1 -share-name
share1 -share-properties continuously-available

cluster1::> vserver cifs share properties remove -vserver vs1 -share-name
share1 -share-properties attributecache

cluster1::> vserver cifs share show -vserver vs1 -share-name share1
-fields symlink-properties,offline-files
vserver  share-name symlink-properties offline-files
-----
vs1      share1    -           manual

cluster1::> vserver cifs share properties show -vserver vs1 -share-name
share1

          Vserver: vs1
          Share: share1
Share Properties: oplocks
                  browsable
                  continuously-available

```

Enable or disable VSS shadow copies for Hyper-V over SMB backups

If you use a VSS-aware backup application to back up Hyper-V virtual machine files stored on SMB shares, VSS shadow copy must be enabled. You can disable the VSS shadow copy if you do not use VSS-aware backup applications. The default is to enable the VSS shadow copy.

About this task

You can enable or disable VSS shadow copies at any time.

Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Perform one of the following actions:

If you want VSS shadow copies to be...	Enter the command...
Enabled	<code>vserver cifs options modify -vserver <i>vserver_name</i> -shadowcopy-enabled true</code>
Disabled	<code>vserver cifs options modify -vserver <i>vserver_name</i> -shadowcopy-enabled false</code>

3. Return to the admin privilege level:

```
set -privilege admin
```

Example

The following commands enable VSS shadow copies on SVM vs1:

```
cluster1::> set -privilege advanced
Warning: These advanced commands are potentially dangerous; use them
only when directed to do so by technical support personnel.
Do you wish to continue? (y or n): y

cluster1::*> vserver cifs options modify -vserver vs1 -shadowcopy-enabled
true

cluster1::*> set -privilege admin
```

Use statistics to monitor Hyper-V and SQL Server over SMB activity

Determine which statistics objects and counters are available

Before you can obtain information about CIFS, SMB, auditing, and BranchCache hash

statistics and monitor performance, you must know which objects and counters are available from which you can obtain data.

Steps

1. Set the privilege level to advanced:

```
set -privilege advanced
```

2. Perform one of the following actions:

If you want to determine...	Enter...
Which objects are available	statistics catalog object show
Specific objects that are available	statistics catalog object show object object_name
Which counters are available	statistics catalog counter show object object_name

See the man pages for more information about which objects and counters are available.

3. Return to the admin privilege level:

```
set -privilege admin
```

Examples

The following command displays descriptions of selected statistic objects related to CIFS and SMB access in the cluster as seen at the advanced privilege level:

```

cluster1::> set -privilege advanced

Warning: These advanced commands are potentially dangerous; use them only
when directed to do so by support personnel.
Do you want to continue? {y|n}: y

cluster1::*> statistics catalog object show -object audit
    audit_ng                      CM object for exporting audit_ng
performance counters

cluster1::*> statistics catalog object show -object cifs
    cifs                          The CIFS object reports activity of the
                                    Common Internet File System protocol
                                    ...
cluster1::*> statistics catalog object show -object nblade_cifs
    nblade_cifs                   The Common Internet File System (CIFS)
                                    protocol is an implementation of the
Server
                                    ...
cluster1::*> statistics catalog object show -object smb1
    smb1                         These counters report activity from the
                                    SMB
                                    revision of the protocol. For information
                                    ...
cluster1::*> statistics catalog object show -object smb2
    smb2                         These counters report activity from the
                                    SMB2/SMB3 revision of the protocol. For
                                    ...
cluster1::*> statistics catalog object show -object hashd
    hashd                        The hashd object provides counters to
measure
                                    the performance of the BranchCache hash
daemon.
cluster1::*> set -privilege admin

```

The following command displays information about some of the counters for the `cifs` object as seen at the advanced privilege level:

This example does not display all of the available counters for the `cifs` object; output is truncated.

```

cluster1::> set -privilege advanced

Warning: These advanced commands are potentially dangerous; use them only
when directed to do so by support personnel.
Do you want to continue? {y|n}: y

cluster1::*> statistics catalog counter show -object cifs

Object: cifs
  Counter          Description
  -----
  -----

```

Display SMB statistics

You can display various SMB statistics to monitor performance and diagnose issues.

Steps

1. Use the `statistics start` and optional `statistics stop` commands to collect a data sample.
2. Perform one of the following actions:

If you want to display statistics for...	Enter the following command...
All versions of SMB	<code>statistics show -object cifs</code>
SMB 1.0	<code>statistics show -object smb1</code>
SMB 2.x and SMB 3.0	<code>statistics show -object smb2</code>
SMB subsystem of the node	<code>statistics show -object nblade_cifs</code>

Learn more about the `statistics` commands:

- [statistics show](#)
- [statistics start](#)
- [statistics stop](#)

Verify that the configuration is capable of nondisruptive operations

Use health monitoring to determine whether nondisruptive operation status is healthy

Health monitoring provides information about system health status across the cluster. The health monitor monitors Hyper-V and SQL Server over SMB configurations to ensure nondisruptive operations (NDOs) for the application servers. If the status is degraded, you can view details about the problem, including the probable cause and recommended recovery actions.

There are several health monitors. ONTAP monitors both overall system health and health for individual health monitors. The node connectivity health monitor contains the CIFS-NDO subsystem. The monitor has a set of health policies that trigger alerts if certain physical conditions can lead to disruption, and if a disruptive condition exists, generates alerts and provides information about corrective actions. For NDO over SMB configurations, alerts are generated for the two following conditions:

Alert ID	Severity	Condition
<code>HaNotReadyCifsNdo_Alert</code>	Major	One or more files hosted by a volume in an aggregate on the node have been opened through a continuously available SMB share with the promise of persistence in the event of a failure; however, the HA relationship with the partner is either not configured or not healthy.

Alert ID	Severity	Condition
NoStandbyLifCifsNdo_Alert	Minor	The storage virtual machine (SVM) is actively serving data over SMB through a node, and there are SMB files opened persistently over continuously available shares; however, its partner node is not exposing any active data LIFs for the SVM.

Display nondisruptive operation status by using system health monitoring

You can use the system health commands to display information about the overall system health of the cluster and the health of the CIFS-NDO subsystem, to respond to alerts, to configure future alerts, and to display information about how health monitoring is configured.

Steps

1. Monitor health status by performing the appropriate action:

If you want to display...	Enter the command...
The health status of the system, which reflects the overall status of individual health monitors	<code>system health status show</code>
Information about the health status of the CIFS-NDO subsystem	<code>system health subsystem show -subsystem CIFS-NDO -instance</code>

2. Display information about how CIFS-NDO alert monitoring is configured by performing the appropriate actions:

If you want to display information about...	Enter the command...
The configuration and status of the health monitor for the CIFS-NDO subsystem, such as nodes monitored, initialization state, and status	<code>system health config show -subsystem CIFS-NDO</code>
The CIFS-NDO alerts that a health monitor can potentially generate	<code>system health alert definition show -subsystem CIFS-NDO</code>
CIFS-NDO health monitor policies, which determine when alerts are raised	<code>system health policy definition show -monitor node-connect</code>

Use the `-instance` parameter to display detailed information.

Examples

The following output shows information about the overall health status of the cluster and the CIFS-NDO subsystem:

```
cluster1::> system health status show
Status
-----
ok

cluster1::> system health subsystem show -instance -subsystem CIFS-NDO
          Subsystem: CIFS-NDO
          Health: ok
          Initialization State: initialized
Number of Outstanding Alerts: 0
Number of Suppressed Alerts: 0
          Node: node2
Subsystem Refresh Interval: 5m
```

The following output shows detailed information about the configuration and status of the health monitor of the CIFS-NDO subsystem:

```

cluster1::> system health config show -subsystem CIFS-NDO -instance

          Node: node1
          Monitor: node-connect
          Subsystem: SAS-connect, HA-health, CIFS-NDO
          Health: ok
          Monitor Version: 2.0
          Policy File Version: 1.0
          Context: node_context
          Aggregator: system-connect
          Resource: SasAdapter, SasDisk, SasShelf,
HaNodePair,
                           HaICMailbox, CifsNdoNode,
CifsNdoNodeVserver
Subsystem Initialization Status: initialized
Subordinate Policy Versions: 1.0 SAS, 1.0 SAS multiple adapters, 1.0,
1.0

          Node: node2
          Monitor: node-connect
          Subsystem: SAS-connect, HA-health, CIFS-NDO
          Health: ok
          Monitor Version: 2.0
          Policy File Version: 1.0
          Context: node_context
          Aggregator: system-connect
          Resource: SasAdapter, SasDisk, SasShelf,
HaNodePair,
                           HaICMailbox, CifsNdoNode,
CifsNdoNodeVserver
Subsystem Initialization Status: initialized
Subordinate Policy Versions: 1.0 SAS, 1.0 SAS multiple adapters, 1.0,
1.0

```

Verify the continuously available SMB share configuration

To support nondisruptive operations, Hyper-V and SQL Server SMB shares must be configured as continuously available shares. Additionally, there are certain other share settings that you must check. You should verify that the shares are properly configured to provide seamless nondisruptive operations for the application servers if there are planned or unplanned disruptive events.

About this task

You must verify that the two following share parameters are set correctly:

- The `-offline-files` parameter is set to either `manual` (the default) or `none`.
- Symlinks must be disabled.

For proper nondisruptive operations, the following share properties must be set:

- `continuously-available`
- `oplocks`

The following share properties must not be set:

- `homedirectory`
- `attribute-cache`
- `branchcache`
- `access-based-enumeration`

Steps

1. Verify that the offline files are set to `manual` or `disabled` and that symlinks are disabled:

```
vserver cifs shares show -vserver vserver_name
```

2. Verify that the SMB shares are configured for continuous availability:

```
vserver cifs shares properties show -vserver vserver_name
```

Examples

The following example displays the share setting for a share named “share1” on storage virtual machine (SVM, formerly known as Vserver) vs1. Offline files are set to `manual` and symlinks are disabled (designated by a hyphen in the `Symlink Properties` field output):

```
cluster1::> vserver cifs share show -vserver vs1 -share-name share1
          Vserver: vs1
          Share: share1
          CIFS Server NetBIOS Name: VS1
          Path: /data/share1
          Share Properties: oplocks
                         continuously-available
          Symlink Properties: -
          File Mode Creation Mask: -
          Directory Mode Creation Mask: -
          Share Comment: -
          Share ACL: Everyone / Full Control
          File Attribute Cache Lifetime: -
          Volume Name: -
          Offline Files: manual
          Vscan File-Operations Profile: standard
```

The following example displays the share properties for a share named “share1” on SVM vs1:

```
cluster1::> vserver cifs share properties show -vserver vs1 -share-name share1
Vserver      Share      Properties
-----      -----
vs1          share1    oplocks
                           continuously-available
```

Verify LIF status

Even if you configure storage virtual machines (SVMs) with Hyper-V and SQL Server over SMB configurations to have LIFs on each node in a cluster, during day-to-day operations, some LIFs might move to ports on another node. You must verify LIF status and take any necessary corrective actions.

About this task

To provide seamless, nondisruptive operation support, each node in a cluster must have at least one LIF for the SVM, and all the LIFs must be associated with a home port. If some of the configured LIFs are not currently associated with their home port, you must fix any port issues and then revert the LIFs to their home port.

Steps

1. Display information about configured LIFs for the SVM:

```
network interface show -vserver vserver_name
```

In this example, “lif1” is not located on the home port.

```
network interface show -vserver vs1
```

Vserver	Logical Interface	Status	Network Address/Mask	Current Node	Current Port	Is Home
vs1	lif1	up/up	10.0.0.128/24	node2	e0d	false
	lif2	up/up	10.0.0.129/24	node2	e0d	true

2. If some of the LIFs are not on their home ports, perform the following steps:

- a. For each LIF, determine what the LIF’s home port is:

```
network interface show -vserver vserver_name -lif lif_name -fields home-node,home-port
```

```
network interface show -vserver vs1 -lif lif1 -fields home-node,home-port
```

```
vserver lif home-node home-port  
-----  
vs1     lif1 node1      e0d
```

- b. For each LIF, determine whether the LIF's home port is up:

```
network port show -node node_name -port port -fields port,link
```

```
network port show -node node1 -port e0d -fields port,link
```

```
node      port link  
-----  
node1    e0d   up
```

In this example, "lif1" should be migrated back to its home port, node1:e0d.

3. If any of the home port network interfaces to which the LIFs should be associated are not in the `up` state, resolve the problem so that these interfaces are up.
4. If needed, revert the LIFs to their home ports:

```
network interface revert -vserver vserver_name -lif lif_name
```

```
network interface revert -vserver vs1 -lif lif1
```

5. Verify that each node in the cluster has an active LIF for the SVM:

```
network interface show -vserver vserver_name
```

```
network interface show -vserver vs1
```

Vserver	Logical Interface	Status	Network Address/Mask	Current Node	Current Port	Is Home
vs1	lif1	up/up	10.0.0.128/24	node1	e0d	true
	lif2	up/up	10.0.0.129/24	node2	e0d	true

Determine whether SMB sessions are continuously available

Display SMB session information

You can display information about established SMB sessions, including the SMB connection and session ID and the IP address of the workstation using the session. You can display information about the session's SMB protocol version and continuously available protection level, which helps you to identify whether the session supports nondisruptive operations.

About this task

You can display information for all of the sessions on your SVM in summary form. However, in many cases, the amount of output that is returned is large. You can customize what information is displayed in the output by specifying optional parameters:

- You can use the optional `-fields` parameter to display output about the fields you choose.

You can enter `-fields ?` to determine what fields you can use.

- You can use the `-instance` parameter to display detailed information about established SMB sessions.
- You can use the `-fields` parameter or the `-instance` parameter either alone or in combination with other optional parameters.

Steps

1. Perform one of the following actions:

If you want to display SMB session information...	Enter the following command...
For all sessions on the SVM in summary form	<code>vserver cifs session show -vserver vserver_name</code>
On a specified connection ID	<code>vserver cifs session show -vserver vserver_name -connection-id integer</code>
From a specified workstation IP address	<code>vserver cifs session show -vserver vserver_name -address workstation_IP_address</code>
On a specified LIF IP address	<code>vserver cifs session show -vserver vserver_name -lif -address LIF_IP_address</code>
On a specified node	<code>vserver cifs session show -vserver vserver_name -node {node_name local}</code>

If you want to display SMB session information...	Enter the following command...
From a specified Windows user	<pre>vserver cifs session show -vserver vserver_name -windows -user user_name</pre> <p>The format for <code>user_name</code> is [domain] \user.</p>
With a specified authentication mechanism	<pre>vserver cifs session show -vserver vserver_name -auth -mechanism authentication_mechanism</pre> <p>The value for <code>-auth-mechanism</code> can be one of the following:</p> <ul style="list-style-type: none"> • NTLMv1 • NTLMv2 • Kerberos • Anonymous
With a specified protocol version	<pre>vserver cifs session show -vserver vserver_name -protocol -version protocol_version</pre> <p>The value for <code>-protocol-version</code> can be one of the following:</p> <ul style="list-style-type: none"> • SMB1 • SMB2 • SMB2_1 • SMB3 • SMB3_1 <p> Continuously available protection and SMB Multichannel are available only on SMB 3.0 and later sessions. To view their status on all qualifying sessions, you should specify this parameter with the value set to SMB3 or later.</p>

If you want to display SMB session information...	Enter the following command...
With a specified level of continuously available protection	<pre>vserver cifs session show -vserver vserver_name -continuously-available continuously_available_protection_level</pre> <p>The value for <code>-continuously-available</code> can be one of the following:</p> <ul style="list-style-type: none"> • No • Yes • Partial <div style="border: 1px solid #ccc; padding: 5px; margin-top: 10px;"> i <p>If the continuously available status is <code>Partial</code>, this means that the session contains at least one open continuously available file, but the session has some files that are not open with continuously available protection. You can use the <code>vserver cifs sessions</code> file show command to determine which files on the established session are not open with continuously available protection.</p> </div>
With a specified SMB signing session status	<pre>vserver cifs session show -vserver vserver_name -is -session-signed {true false}</pre>

Examples

The following command displays session information for the sessions on SVM vs1 established from a workstation with IP address 10.1.1.1:

```
cluster1::> vserver cifs session show -address 10.1.1.1
Node:    node1
Vserver: vs1
Connection Session                                Open      Idle
ID        ID      Workstation      Windows User   Files     Time
-----  -----
3151272279,
3151272280,
3151272281  1          10.1.1.1           DOMAIN\joe      2         23s
```

The following command displays detailed session information for sessions with continuously available protection on SVM vs1. The connection was made by using the domain account.

```
cluster1::> vserver cifs session show -instance -continuously-available
Yes

          Node: node1
          Vserver: vs1
          Session ID: 1
          Connection ID: 3151274158
Incoming Data LIF IP Address: 10.2.1.1
          Workstation IP address: 10.1.1.2
          Authentication Mechanism: Kerberos
          Windows User: DOMAIN\SERVER1$
          UNIX User: pcuser
          Open Shares: 1
          Open Files: 1
          Open Other: 0
          Connected Time: 10m 43s
          Idle Time: 1m 19s
          Protocol Version: SMB3
Continuously Available: Yes
          Is Session Signed: false
          User Authenticated as: domain-user
          NetBIOS Name: -
SMB Encryption Status: Unencrypted
```

The following command displays session information on a session using SMB 3.0 and SMB Multichannel on SVM vs1. In the example, the user connected to this share from an SMB 3.0 capable client by using the LIF IP address; therefore, the authentication mechanism defaulted to NTLMv2. The connection must be made by using Kerberos authentication to connect with continuously available protection.

```
cluster1::> vserver cifs session show -instance -protocol-version SMB3

        Node: node1
        Vserver: vs1
        Session ID: 1
        **Connection IDs: 3151272607,31512726078,3151272609
        Connection Count: 3**
Incoming Data LIF IP Address: 10.2.1.2
        Workstation IP address: 10.1.1.3
Authentication Mechanism: NTLMv2
        Windows User: DOMAIN\administrator
        UNIX User: pcuser
        Open Shares: 1
        Open Files: 0
        Open Other: 0
        Connected Time: 6m 22s
        Idle Time: 5m 42s
        Protocol Version: SMB3
Continuously Available: No
        Is Session Signed: false
User Authenticated as: domain-user
        NetBIOS Name: -
SMB Encryption Status: Unencrypted
```

Display information about open SMB files

You can display information about open SMB files, including the SMB connection and session ID, the hosting volume, the share name, and the share path. You can also display information about the continuously available protection level of a file, which is helpful in determining whether an open file is in a state that supports nondisruptive operations.

About this task

You can display information about open files on an established SMB session. The displayed information is useful when you need to determine SMB session information for particular files within an SMB session.

For example, if you have an SMB session where some of the open files are open with continuously available protection and some are not open with continuously available protection (the value for the `-continuously-available` field in `vserver cifs session show` command output is `Partial`), you can determine which files are not continuously available by using this command.

You can display information for all open files on established SMB sessions on storage virtual machines (SVMs) in summary form by using the `vserver cifs session file show` command without any optional parameters.

However, in many cases, the amount of output returned is large. You can customize what information is displayed in the output by specifying optional parameters. This can be helpful when you want to view information for only a small subset of open files.

- You can use the optional `-fields` parameter to display output on the fields you choose.

You can use this parameter either alone or in combination with other optional parameters.

- You can use the `-instance` parameter to display detailed information about open SMB files.

You can use this parameter either alone or in combination with other optional parameters.

Steps

1. Perform one of the following actions:

If you want to display open SMB files...	Enter the following command...
On the SVM in summary form	<code>vserver cifs session file show -vserver vserver_name</code>
On a specified node	<code>vserver cifs session file show -vserver vserver_name -node {node_name local}</code>
On a specified file ID	<code>vserver cifs session file show -vserver vserver_name -file-id integer</code>
On a specified SMB connection ID	<code>vserver cifs session file show -vserver vserver_name -connection-id integer</code>
On a specified SMB session ID	<code>vserver cifs session file show -vserver vserver_name -session-id integer</code>
On the specified hosting aggregate	<code>vserver cifs session file show -vserver vserver_name -hosting -aggregate aggregate_name</code>
On the specified volume	<code>vserver cifs session file show -vserver vserver_name -hosting-volume volume_name</code>
On the specified SMB share	<code>vserver cifs session file show -vserver vserver_name -share share_name</code>
On the specified SMB path	<code>vserver cifs session file show -vserver vserver_name -path path</code>

If you want to display open SMB files...	Enter the following command...
With the specified level of continuously available protection	<pre>vserver cifs session file show -vserver vserver_name -continuously -available continuously_available_status</pre> <p>The value for <code>-continuously-available</code> can be one of the following:</p> <ul style="list-style-type: none"> • No • Yes <p></p> <p>If the continuously available status is <code>No</code>, this means that these open files are not capable of nondisruptively recovering from takeover and giveback. They also cannot recover from general aggregate relocation between partners in a high-availability relationship.</p>
With the specified reconnected state	<pre>vserver cifs session file show -vserver vserver_name -reconnected reconnected_state</pre> <p>The value for <code>-reconnected</code> can be one of the following:</p> <ul style="list-style-type: none"> • No • Yes <p></p> <p>If the reconnected state is <code>No</code>, the open file is not reconnected after a disconnection event. This can mean that the file was never disconnected, or that the file was disconnected and is not successfully reconnected. If the reconnected state is <code>Yes</code>, this means that the open file is successfully reconnected after a disconnection event.</p>

There are additional optional parameters that you can use to refine the output results. See the man page for more information.

Examples

The following example displays information about open files on SVM vs1:

```
cluster1::> vserver cifs session file show -vserver vs1
Node:      node1
Vserver:   vs1
Connection: 3151274158
Session:   1
File      File      Open Hosting          Continuously
ID        Type       Mode Volume       Share
-----  -----
41       Regular    r     data       data      Available
Path: \mytest.rtf
```

The following example displays detailed information about open SMB files with file ID 82 on SVM vs1:

```
cluster1::> vserver cifs session file show -vserver vs1 -file-id 82
-instance

          Node: node1
          Vserver: vs1
          File ID: 82
          Connection ID: 104617
          Session ID: 1
          File Type: Regular
          Open Mode: rw
Aggregate Hosting File: aggr1
Volume Hosting File: data1
CIFS Share: data1
Path from CIFS Share: windows\win8\test\test.txt
Share Mode: rw
Range Locks: 1
Continuously Available: Yes
Reconnected: No
```

SAN storage management

SAN administration

SAN provisioning

SAN management overview

The content in this section shows you how to configure and manage SAN environments with the ONTAP command line interface (CLI) and System Manager in ONTAP 9.7 and later releases.

If you are using the classic System Manager (available only in ONTAP 9.7 and earlier), see these topics:

- [iSCSI protocol](#)
- [FC/FCoE protocol](#)

You can use the iSCSI and FC protocols to provide storage in a SAN environment.

With iSCSI and FC, storage targets are called LUNs (logical units) and are presented to hosts as standard

block devices. You create LUNs and then map them to initiator groups (igroups). Initiator groups are tables of FC host WWPs and iSCSI host node names and control which initiators have access to which LUNs.

FC targets connect to the network through FC switches and host-side adapters and are identified by world-wide port names (WWPNs). iSCSI targets connect to the network through standard Ethernet network adapters (NICs), TCP offload engine (TOE) cards with software initiators, converged network adapters (CNAs) or dedicated host bus adapters (HBAs) and are identified by iSCSI qualified names (IQNs).

Configure switches for FCoE

You must configure your switches for FCoE before your FC service can run over the existing Ethernet infrastructure.

What you'll need

- Your SAN configuration must be supported.

For more information about supported configurations, see the [NetApp Interoperability Matrix Tool](#).

- A Unified Target Adapter (UTA) must be installed on your storage system.

If you are using a UTA2, it must be set to cna mode.

- A converged network adapter (CNA) must be installed on your host.

Steps

1. Use your switch documentation to configure your switches for FCoE.
2. Use the `dcb show` command to verify that the DCB settings for each node in the cluster have been correctly configured.

```
run -node node1 -command dcb show
```

DCB settings are configured on the switch. Consult your switch documentation if the settings are incorrect.

3. Use the `fcp adapter show` command to verify that the FCoE login is working when the FC target port online status is true.

```
cluster1::> fcp adapter show -fields node,adapter,status,state,speed,fabric-established,physical-protocol
```

If the FC target port online status is false, consult your switch documentation.

System Requirements

Setting up LUNs involves creating a LUN, creating an igroup, and mapping the LUN to the igroup. Your system must meet certain prerequisites before you can set up your LUNs.

- The Interoperability Matrix must list your SAN configuration as supported.
- Your SAN environment must meet the SAN host and controller configuration limits specified in [NetApp Hardware Universe](#) for your version of the ONTAP software.
- A supported version of Host Utilities must be installed.

The Host Utilities documentation provides more information.

- You must have SAN LIFs on the LUN owning node and the owning node's HA partner.

What to know before you create a LUN

Why actual LUN sizes slightly vary

You should be aware of the following regarding the size of your LUNs.

- When you create a LUN , the actual size of the LUN might vary slightly based on the OS type of the LUN. The LUN OS type cannot be modified after the LUN is created.
- If you create a LUN at the max LUN size, be aware that the actual size of the LUN might be slightly less. ONTAP rounds down the limit to be slightly less.
- The metadata for each LUN requires approximately 64 KB of space in the containing aggregate. When you create a LUN, you must ensure that the containing aggregate has enough space for the LUN's metadata. If the aggregate does not contain enough space for the LUN's metadata, some hosts might not be able to access the LUN.

Guidelines for assigning LUN IDs

Typically, the default LUN ID begins with 0 and is assigned in increments of 1 for each additional mapped LUN. The host associates the LUN ID with the location and path name of the LUN. The range of valid LUN ID numbers depends on the host. For detailed information, see the documentation provided with your Host Utilities.

Guidelines for mapping LUNs to igroups

- You can map a LUN only once to an igroup.
- As a best practice, you should map a LUN to only one specific initiator through the igroup.
- You can add a single initiator to multiple igroups, but the initiator can be mapped to only one LUN.
- You cannot use the same LUN ID for two LUNs mapped to the same igroup.

- You should use the same protocol type for igroups and port sets.

Verify and add your protocol FC or iSCSI license

Before you can enable block access for a storage virtual machine (SVM) with FC or iSCSI, you must have a license.

Example 2. Steps

System Manager

Verify and add your FC or iSCSI license with ONTAP System Manager (9.7 and later).

1. In System Manager, select **Cluster > Settings > Licenses**
2. If the license is not listed, select  and enter the license key.
3. Select **Add**.

CLI

Verify and add your FC or iSCSI license with the ONTAP CLI.

1. Verify that you have a active license for FC or iSCSI.

```
system license show
```

Package	Type	Description	Expiration
<hr/>			
<hr/>			
Base	site	Cluster Base License	-
NFS	site	NFS License	-
CIFS	site	CIFS License	-
iSCSI	site	iSCSI License	-
FCP	site	FCP License	-

2. If you do not have a active license for FC or iSCSI, add your license code.

```
license add -license-code your_license_code
```

Provision SAN storage

This procedure creates new LUNs on an existing storage VM which already has the FC or iSCSI protocol configured.

If you need to create a new storage VM and configure the FC or iSCSI protocol, see [Configure an SVM for FC](#) or [Configure an SVM for iSCSI](#).

If the FC license is not enabled, the LIFs and SVMs appear to be online but the operational status is down.

LUNs appear to your host as disk devices.

Asymmetric logical unit access (ALUA) is always enabled during LUN creation. You cannot change the ALUA setting.

You must use single initiator zoning for all of the FC LIFs in the SVM to host the initiators.

Unresolved directive in san-admin/provision-storage.adoc -
include::_include/98_qos_enabled_by_default.adoc[]

Example 3. Steps

System Manager

Create LUNs to provide storage for a SAN host using the FC or iSCSI protocol with ONTAP System Manager (9.7 and later).

To complete this task using System Manager Classic (available with 9.7 and earlier) refer to [iSCSI configuration for Red Hat Enterprise Linux](#)

Steps

1. Install the appropriate [SAN host utilities](#) on your host.
2. In System Manager, click **Storage > LUNs** and then click **Add**.
3. Enter the required information to create the LUN.

Unresolved directive in san-admin/provision-storage.adoc -
include::_include/san_add_lun_more_options.adoc[]

5. For FC, zone your FC switches by WWPN. Use one zone per initiator and include all target ports in each zone.
6. Discover LUNs on your host.

For VMware vSphere, use Virtual Storage Console (VSC) to discover and initialize your LUNs.

7. Initialize the LUNs and optionally, create file systems.
8. Verify that the host can write and read data on the LUN.

CLI

Create LUNs to provide storage for a SAN host using the FC or iSCSI protocol with the ONTAP CLI.

1. Verify that you have a license for FC or iSCSI.

```
system license show
```

Package	Type	Description	Expiration
Base	site	Cluster Base License	-
NFS	site	NFS License	-
CIFS	site	CIFS License	-
iSCSI	site	iSCSI License	-
FCP	site	FCP License	-

2. If you do not have a license for FC or iSCSI, use the `license add` command.

```
license add -license-code <your_license_code>
```

3. Enable your protocol service on the SVM:

For iSCSI:

```
vserver iscsi create -vserver <svm_name> -target-alias <svm_name>
```

For FC:

```
vserver fcp create -vserver <svm_name> -status-admin up
```

4. Create two LIFs for the SVMs on each node:

```
network interface create -vserver <svm_name> -lif <lif_name> -role data -data-protocol <iscsi|fc> -home-node <node_name> -home-port <port_name> -address <ip_address> -netmask <netmask>
```

NetApp supports a minimum of one iSCSI or FC LIF per node for each SVM serving data. However, two LIFs per node are required for redundancy.

5. Verify that your LIFs have been created and that their operational status is online:

```
network interface show -vserver <svm_name> <lif_name>
```

6. Create your LUNs:

```
lun create -vserver <svm_name> -volume <volume_name> -lun <lun_name> -size <lun_size> -ostype linux -space-reserve <enabled|disabled>
```

Your LUN name cannot exceed 255 characters and cannot contain spaces.

The NVFAIL option is automatically enabled when a LUN is created in a volume.

7. Create your igroups:

```
igroup create -vserver <svm_name> -igroup <igroup_name> -protocol <fcp|iscsi|mixed> -ostype linux -initiator <initiator_name>
```

8. Map your LUNs to igroups:

```
lun mapping create -vserver <svm_name> -volume <volume_name> -lun <lun_name> -igroup <igroup_name>
```

9. Verify that your LUNs are configured correctly:

```
lun show -vserver <svm_name>

. Optionally, xref:{relative\_path}create-port-sets-binding-igroups-task.html[Create a port set and bind to an igroup].

. Follow steps in your host documentation for enabling block access on your specific hosts.

. Use the Host Utilities to complete the FC or iSCSI mapping and to discover your LUNs on the host.
```

NVMe provisioning

NVMe Overview

You can use the non-volatile memory express (NVMe) protocol to provide storage in a SAN environment. The NVMe protocol is optimized for performance with solid state storage.

For NVMe, storage targets are called namespaces. An NVMe namespace is a quantity of non-volatile storage that can be formatted into logical blocks and presented to a host as a standard block device. You create namespaces and subsystems, and then map the namespaces to the subsystems, similar to the way LUNs are provisioned and mapped to igroups for FC and iSCSI.

NVMe targets are connected to the network through a standard FC infrastructure using FC switches or a standard TCP infrastructure using Ethernet switches and host-side adapters.

Support for NVMe varies based on your version of ONTAP. See [NVMe support and limitations](#) for details.

What NVMe is

The nonvolatile memory express (NVMe) protocol is a transport protocol used for accessing nonvolatile storage media.

NVMe over Fabrics (NVMeoF) is a specification-defined extension to NVMe that enables NVMe-based communication over connections other than PCIe. This interface allows for external storage enclosures to be connected to a server.

NVMe is designed to provide efficient access to storage devices built with non-volatile memory, from flash technology to higher performing, persistent memory technologies. As such, it does not have the same limitations as storage protocols designed for hard disk drives. Flash and solid state devices (SSDs) are a type

of non-volatile memory (NVM). NVM is a type of memory that keeps its content during a power outage. NVMe is a way that you can access that memory.

The benefits of NVMe include increased speeds, productivity, throughput, and capacity for data transfer. Specific characteristics include the following:

- NVMe is designed to have up to 64 thousand queues.

Each queue in turn can have up to 64 thousand concurrent commands.

- NVMe is supported by multiple hardware and software vendors
- NVMe is more productive with Flash technologies enabling faster response times
- NVMe allows for multiple data requests for each “request” sent to the SSD.

NVMe takes less time to decode a “request” and does not require thread locking in a multithreaded program.

- NVMe supports functionality that prevents bottlenecking at the CPU level and enables massive scalability as systems expand.

About NVMe namespaces

An NVMe namespace is a quantity of non-volatile memory (NVM) that can be formatted into logical blocks. Namespaces are used when a storage virtual machine is configured with the NVMe protocol and are the equivalent of LUNs for FC and iSCSI protocols.

One or more namespaces are provisioned and connected to an NVMe host. Each namespace can support various block sizes.

The NVMe protocol provides access to namespaces through multiple controllers. Using NVMe drivers, which are supported on most operating systems, solid state drive (SSD) namespaces appear as standard-block devices on which file systems and applications can be deployed without any modification.

A namespace ID (NSID) is an identifier used by a controller to provide access to a namespace. When setting the NSID for a host or host group, you also configure the accessibility to a volume by a host. A logical block can only be mapped to a single host group at a time, and a given host group does not have any duplicate NSIDs.

About NVMe subsystems

An NVMe subsystem includes one or more NVMe controllers, namespaces, NVM subsystem ports, an NVM storage medium, and an interface between the controller and the NVM storage medium. When you create an NVMe namespace, by default it is not mapped to a subsystem. You can also choose to map it a new or existing subsystem.

Related information

- [Provision NVMe storage for SUSE Linux](#)
- [Provision NVMe storage for other hosts](#)
- [Map an NVMe namespace to a subsystem](#)

NVMe license requirements

Beginning with ONTAP 9.5 a license is required to support NVMe. If NVMe is enabled in

ONTAP 9.4, a 90 day grace period is given to acquire the license after upgrading to ONTAP 9.5.

You can enable the license using the following command:

```
system license add -license-code NVMe_license_key
```

NVMe support and limitations

NVMe support and limitations varies based on your version of ONTAP, your platform and your configuration.

Protocol support

Protocol	Beginning with ...	Allowed by...
TCP	ONTAP 9.10.1	Default
FC	ONTAP 9.4	Default

Platform and configuration support and limitations

Support for NVMe-oF protocol varies by platform and configuration. For details on your specific configuration, see the [NetApp Interoperability Matrix Tool](#).

Beginning with ONTAP 9.12.1, 4-node MetroCluster IP configurations are supported on NVMe/FC. MetroCluster configurations are not supported for NVMe prior to 9.12.1.

Beginning with ONTAP...	Platforms
9.12.1	<ul style="list-style-type: none">FASAll Flash FAS (AFF)All SAN Array (ASA) platforms
9.9.1	<ul style="list-style-type: none">AFFASA
9.4	AFF platforms only

Namespace support and limitations

To set up the NVMe protocol in your SAN environment, you must configure an SVM for NVMe, create namespaces and subsystems, configure an NVMe/FC LIF, and then map the namespaces to the subsystems. When working with NVMe namespaces you should be aware of the following:

- Beginning with ONTAP 9.10.1, you can [resize a namespace](#). Resizing a namespace is not supported in releases prior to ONTAP 9.10.1.
- Beginning with ONTAP 9.6, namespaces support 512 byte blocks and 4096 byte blocks.

4096 is the default value. 512 should only be used if the host operating system does not support 4096 byte blocks.

- If you lose data in a LUN, it cannot be restored from a namespace, or vice versa.
- The space guarantee for namespaces is the same as the space guarantee of the containing volume.
- Namespaces do not support the following:
 - Renaming

You cannot rename a namespace.

- Inter-volume move
- Inter-volume copy

Configure a storage VM for NVMe

If you want to use the NVMe protocol on a node, you must configure your SVM specifically for NVMe.

What you'll need

Your FC or Ethernet adapters must support NVMe. Supported adapters are listed in the [NetApp Hardware Universe](#).

Example 4. Steps

System Manager

Configure an storage VM for NVMe with ONTAP System Manager (9.7 and later).

To configure NVMe on a new storage VM	To configure NVMe on an existing storage VM
<ol style="list-style-type: none">1. In System Manager, click Storage > Storage VMs and then click Add.2. Enter a name for the storage VM.3. Select NVMe for the Access Protocol.4. Select Enable NVMe/FC or Enable NVMe/TCP and Save.	<ol style="list-style-type: none">1. In System Manager, click Storage > Storage VMs.2. Click on the storage VM you want to configure.3. Click on the Settings tab, and then click  next to the NVMe protocol.4. Select Enable NVMe/FC or Enable NVMe/TCP and Save.

CLI

Configure an storage VM for NVMe with the ONTAP CLI.

1. If you do not want to use an existing SVM, create one:

```
vserver create -vserver SVM_name
```

- a. Verify that the SVM is created:

```
vserver show
```

2. Verify that you have NVMe or TCP capable adapters installed in your cluster:

```
For NVMe: network fcp adapter show -data-protocols-supported fc-nvme
```

```
For TCP: network port show
```

3. If you are running ONTAP 9.7 or earlier, remove all protocols from the SVM:

```
vserver remove-protocols -vserver SVM_name -protocols  
iscsi,fcp,nfs,cifs,ndmp
```

Beginning with ONTAP 9.8, it is not necessary to remove other protocols when adding NVMe.

4. Add the NVMe protocol to the SVM:

```
vserver add-protocols -vserver SVM_name -protocols nvme
```

5. If you are running ONTAP 9.7 or earlier, verify that NVMe is the only protocol allowed on the SVM:

```
vserver show -vserver SVM_name -fields allowed-protocols
```

NVMe should be the only protocol displayed under the `allowed_protocols` column.

6. Create the NVMe service:

```
vserver nvme create -vserver SVM_name
```

7. Verify that the NVMe service was created:

```
vserver nvme show -vserver SVM_name
```

The Administrative Status of the SVM should be listed as up.

8. Create an NVMe/FC LIF:

ONTAP version	Applicable protocols	Command
ONTAP 9.9.1 or earlier	FC	<pre>network interface create -vserver SVM_name -lif lif_name -role data -data-protocol fc-nvme -home-node home_node -home-port home_port</pre>
ONTAP 9.10.1	FC or TCP	<pre>network interface create -vserver SVM_name -lif lif_name -service-policy {default-data-nvme-tcp default-data-nvme-fc} -home-node home_node -home-port home_port -status admin up -failover-policy disabled -firewall -policy data -auto -revert false -failover -group failover_group -is-dns-update-enabled false</pre>

9. Create an NVMe/FC LIF on the HA partner node:

ONTAP version	Applicable protocols	Command
ONTAP 9.9.1 or earlier	FC	<pre>network interface create -vserver SVM_name -lif lif_name -role data -data-protocol fc-nvme -home-node home_node -home-port home_port</pre>

ONTAP version	Applicable protocols	Command
ONTAP 9.10.1 or later	FC or TCP	<pre>network interface create -vserver SVM_name -lif lif_name -service-policy {default-data-nvme-tcp default-data-nvme-fc} -home-node home_node -home-port home_port -status admin up -failover-policy disabled -firewall -policy data -auto -revert false -failover -group failover_group -is-dns-update-enabled false</pre>

10. Verify the NVMe/FC LIFs were created:

```
network interface show -vserver SVM_name
```

11. Create volume on the same node as the LIF:

```
vol create -vserver SVM_name -volume vol_name -aggregate aggregate_name
-size volume_size
```

If a warning message is displayed about the auto efficiency policy, it can be safely ignored.

Provision NVMe storage

If a procedure for your specific host is not available, you can use these steps to create namespaces and provision storage for any NVMe supported host.

This procedure creates new namespaces on an existing storage VM. Your storage VM must be configured for NVME, and your FC or TCP transport should already be set up.

Beginning with ONTAP 9.8, when you provision storage, QoS is enabled by default. You can disable QoS or choose a custom QoS policy during the provisioning process or at a later time.

System Manager

Using ONTAP System Manager (9.7 and later), create namespaces to provide storage using the NVMe protocol.

Steps

1. In System Manager, click **Storage > NVMe Namespaces** and then click **Add**.
If you need to create a new subsystem, click **More Options**.
2. If you are running ONTAP 9.8 or later and you want to disable QoS or choose a custom QoS policy, click **More Options** and then, under **Storage and Optimization** select **Performance Service Level**.
3. Zone your FC switches by WWPN. Use one zone per initiator and include all target ports in each zone.
4. On your host, discover the new namespaces.
5. Initialize the namespace and format it with a file system.
6. Verify that your host can write and read data on the namespace.

CLI

Using the ONTAP CLI, create namespaces to provide storage using the NVMe protocol.

This procedure creates an NVMe namespace and subsystem on an existing storage VM which has already been configured for the NVMe protocol, then maps the namespace to the subsystem to allow data access from your host system.

If you need to configure the storage VM for NVMe, see [Configure an SVM for NVMe](#).

Steps

1. Verify that the SVM is configured for NVMe:

```
vserver show -vserver <svm_name> -fields allowed-protocols
```

NVMe should be displayed under the allowed-protocols column.

2. Create the NVMe namespace:

```
vserver nvme namespace create -vserver <svm_name> -path <path> -size <size_of_namespace> -ostype <OS_type>
```

3. Create the NVMe subsystem:

```
vserver nvme subsystem create -vserver <svm_name> -subsystem <name_of_subsystem> -ostype <OS_type>
```

The NVMe subsystem name is case sensitive. It must contain 1 to 96 characters. Special characters are allowed.

4. Verify that the subsystem was created:

```
vserver nvme subsystem show -vserver <svm_name>
```

The nvme subsystem should be displayed under the Subsystem column.

5. Obtain the NQN from the host.

6. Add the host NQN to the subsystem:

```
vserver nvme subsystem host add -vserver <svm_name> -subsystem <subsystem_name> -host-nqn <Host_NQN>
```

7. Map the namespace to the subsystem:

```
vserver nvme subsystem map add -vserver <svm_name> -subsystem <subsystem_name> -path <path>
```

A namespace can only be mapped to a single subsystem.

8. Verify that the namespace is mapped to the subsystem:

```
vserver nvme namespace show -vserver <svm_name> -instance
```

The subsystem should be listed as the Attached subsystem.

Map an NVMe namespace to a subsystem

This procedure maps an existing NVMe namespace to an existing NVMe subsystem using the ONTAP CLI.

Your namespace and subsystem should already be created. If you need to create a namespace and subsystem, see [Provision NVMe storage](#).

Steps

1. Obtain the NQN from the host.

2. Add the host NQN to the subsystem:

```
vserver nvme subsystem host add -vserver SVM_name -subsystem subsystem_name -host-nqn Host_NQN:subsystem.subsystem_name
```

3. Map the namespace to the subsystem:

```
vserver nvme subsystem map add -vserver SVM_name -subsystem subsystem_name -path path
```

A namespace can only be mapped to a single subsystem.

4. Verify that the namespace is mapped to the subsystem:

```
vserver nvme namespace show -vserver SVM_name -instance
```

The subsystem should be listed as the Attached subsystem.

Manage LUNs

Edit LUN QoS policy group

Beginning with ONTAP 9.10.1, you can use System Manager to assign or remove Quality of Service (QoS) policies on multiple LUNs at the same time.

If the QoS policy is assigned at the volume level, it must be changed at the volume level. You can only edit the QoS policy at the LUN level if it was originally assigned at the LUN level.

Steps

1. In System Manager, click **Storage > LUNs**.
2. Select the LUN or LUNs you want to edit.

If you are editing more than one LUN at a time, the LUNs must belong to the same Storage Virtual Machine (SVM). If you select LUNs that do not belong to the same SVM, the option to edit the QoS Policy Group is not displayed.

3. Click **More** and select **Edit QoS Policy Group**.

Convert a LUN into a namespace

Beginning with ONTAP 9.11.1, you can use the ONTAP CLI to in-place convert an existing LUN to an NVMe namespace.

What you'll need

- Specified LUN should not have any existing maps to an igroup.
- LUN should not be in a MetroCluster configured SVM or in an SM-BC relationship.
- LUN should not be a protocol endpoint or bound to a protocol endpoint.
- LUN should not have non-zero prefix and/or suffix stream.
- LUN should not be part of a snapshot or on the destination side of SnapMirror relationship as a read-only LUN.

Steps

1. You enter the following command to convert a LUN to an NVMe namespace:

```
vserver nvme namespace convert-from-lun -vserver -lun-path
```

Take a LUN offline

Beginning with ONTAP 9.10.1 you can use System Manager to take LUNs offline. Prior to ONTAP 9.10.1, you must use the ONTAP CLI to take LUNs offline.

System Manager

Steps

1. In System Manager, click **Storage>LUNs**.
2. Take a single LUN or multiple LUNs offline

If you want to...	Do this...
Take a single LUN offline	Next to the LUN name, click  and select Take Offline .
Take multiple LUNs offline	<ol style="list-style-type: none">Select the LUNs you want to take offline.Click More and select Take Offline.

CLI

You can only take one LUN offline at a time when using the CLI.

Step

1. Take the LUN offline: `lun offline lun_name -vserver SVM_name`

Resize a LUN

You can increase or decrease the size of a LUN.

Solaris LUNs cannot be resized.

Increase the size of a LUN

The size to which you can increase your LUN varies depending upon your version of ONTAP.

ONTAP version	Maximum LUN size
ONTAP 9.8 and later	<ul style="list-style-type: none">• 128 TB for All SAN Arrays (ASAs)• 16 TB for non-ASAs
ONTAP 9.5, 9.6, 9.7	16TB

ONTAP 9.4 or earlier	<p>10 times the original LUN size, but not greater than 16TB, which is the maximum LUN size.</p> <p>For example, if you create a 100 GB LUN, you can only grow it to 1,000 GB.</p> <p>The actual maximum size of the LUN might not be exactly 16TB. ONTAP rounds down the limit to be slightly less.</p>
----------------------	--

You do not need to take the LUN offline to increase the size. However, after you have increased the size, you must rescan the LUN on the host for the host to recognize the change in size.

See the Command Reference page for the `lun resize` command for more information about resizing a LUN.

Example 5. Steps

System Manager

Increase the size of a LUN with ONTAP System Manager (9.7 and later).

1. In System Manager, click **Storage > LUNs**.
2. Click  and select **Edit**.
3. Under **Storage and Optimization** increase the size of the LUN and **Save**.

CLI

Increase the size of a LUN with the ONTAP CLI.

1. Increase the size of the LUN:

```
lun resize -vserver vserver_name -volume volume_name -lun lun_name -size
lun_size
```

2. Verify the increased LUN size:

```
lun show -vserver vserver_name
```

ONTAP operations round down the actual maximum size of the LUN so it is slightly less than the expected value. Also, actual LUN size might vary slightly based on the OS type of the LUN. To obtain the exact resized value, run the following commands in advanced mode:

```
set -unit B
```

```
lun show -fields max-resize-size -volume volume_name -lun
lun_name
```

3. Rescan the LUN on the host.
4. Follow your host documentation to make the newly created LUN size visible to the host file system.

Decrease the size of a LUN

Before you decrease the size of a LUN, the host needs to migrate the blocks containing the LUN data into the boundary of the smaller LUN size. You should use a tool such as SnapDrive for Windows to ensure that the LUN is properly decreased without truncating blocks containing LUN data. Manually decreasing the size of your LUN is not recommended.

After you decrease the size of your LUN, ONTAP automatically notifies the initiator that the LUN size has decreased. However, additional steps might be required on your host for the host to recognize the new LUN size. Check your host documentation for specific information about decreasing the size of the host file structure.

Move a LUN

You can move a LUN across volumes within a storage virtual machine (SVM), but you cannot move a LUN across SVMs. LUNs moved across volumes within an SVM are moved immediately and without loss of connectivity.

What you'll need

If your LUN is using Selective LUN Map (SLM), the SLM reporting nodes must have been modified to include the destination node and its HA partner.

About this task

Storage efficiency features, such as deduplication, compression, and compaction are not preserved during a LUN move. They must be reapplied after the LUN move is completed.

Data protection through Snapshot copies occurs at the volume level. Therefore, when you move a LUN, it falls under the data protection scheme of the destination volume. If you do not have Snapshot copies established for the destination volume, Snapshot copies of the LUN are not created. Also, all of the Snapshot copies of the LUN stay in the original volume until those Snapshot copies are deleted.

You cannot move a LUN to the following volumes:

- A SnapMirror destination volume
- The SVM root volume

You cannot move the following types of LUNs:

- A LUN that has been created from a file
- A LUN that is in NVFail state
- A LUN that is in a load-sharing relationship
- A protocol-endpoint class LUN

For Solaris os_type LUNs that are 1 TB or larger, the host might experience a timeout during the LUN move. For this LUN type, you should unmount the LUN before initiating the move.

Example 6. Steps

System Manager

Move a LUN with ONTAP System Manager (9.7 and later).

Beginning with ONTAP 9.10.1, you can use System Manager to create a new volume when you move a single LUN. In ONTAP 9.8 and 9.9.1, the volume to which you are moving your LUN must exist before you begin the LUN move.

Steps

1. In System Manager, click **Storage>LUNs**.
2. Right click the LUN you want to move, then click  and select **Move LUN**.

In ONTAP 9.10.1, select to move the LUN to **An existing volume** or to a **New volume**.

If you select to create a new volume, provide the volume specifications.

3. Click **Move**.

CLI

Move a LUN with the ONTAP CLI.

1. Move the LUN:

```
lun move start.
```

During a very brief period, the LUN is visible on both the origin and destination volume. This is expected and is resolved upon completion of the move.

2. Track the status of the move and verify successful completion:

```
lun move show.
```

Related information

- [Selective LUN Map](#)
- [Modifying the SLM reporting-nodes list](#)

Delete LUNs

You can delete a LUN from a storage virtual machine (SVM) if you no longer need the LUN.

What you'll need

The LUN must be unmapped from its igroup before you can delete it.

Steps

1. Verify that the application or host is not using the LUN.
2. Unmap the LUN from the igroup:

```
lun mapping delete  
lun mapping delete -vserver vs5 -volume vo5 -lun lun5 -igroup igr5
```

3. Delete the LUN:

```
lun delete  
lun delete -vserver vs5 -volume vol5 -lun lun5
```

4. Verify that you deleted the LUN:

```
lun show  
lun show -vserver vs5
```

Vserver	Path	State	Mapped	Type	Size
vs5	/vol/vol16/lun8	online	mapped	windows	10.00GB

What to know before copying LUNs

You should be aware of certain things before copying a LUN.

Cluster administrators can copy a LUN across storage virtual machines (SVMs) within the cluster by using the `lun copy` command. Cluster administrators must establish the storage virtual machine (SVM) peering relationship using the `vserver peer create` command before an inter-SVM LUN copy operation is performed. There must be enough space in the source volume for a SIS clone.

LUNs in Snapshot copies can be used as source LUNs for the `lun copy` command. When you copy a LUN using the `lun copy` command, the LUN copy is immediately available for read and write access. The source LUN is unchanged by creation of a LUN copy. Both the source LUN and the LUN copy exist as unique LUNs with different LUN serial numbers. Changes made to the source LUN are not reflected in the LUN copy, and changes made to the LUN copy are not reflected in the source LUN. The LUN mapping of the source LUN is not copied to the new LUN; the LUN copy must be mapped.

Data protection through Snapshot copies occurs at the volume level. Therefore, if you copy a LUN to a volume different from the volume of the source LUN, the destination LUN falls under the data protection scheme of the destination volume. If you do not have Snapshot copies established for the destination volume, Snapshot copies are not created of the LUN copy.

Copying LUNs is a nondisruptive operation.

You cannot copy the following types of LUNs:

- A LUN that has been created from a file
- A LUN that is in NVFAIL state
- A LUN that is in a load-sharing relationship
- A protocol-endpoint class LUN

Examine configured and used space of a LUN

Knowing the configured space and actual space used for your LUNs can help you determine the amount of space that can be reclaimed when doing space reclamation, the amount of reserved space that contains data, and the total configured size versus the actual size used for a LUN.

Step

1. View the configured space versus the actual space used for a LUN:

```
lun show
```

The following example show the configured space versus the actual space used by the LUNs in the vs3 storage virtual machine (SVM):

```
lun show -vserver vs3 -fields path, size, size-used, space-reserve
```

vserver	path	size	space-reserve	size-used
vs3	/vol/vol0/lun1	50.01GB	disabled	25.00GB
vs3	/vol/vol0/lun1_backup	50.01GB	disabled	32.15GB
vs3	/vol/vol0/lun2	75.00GB	disabled	0B
vs3	/vol/vospace/lun0	5.00GB	enabled	4.50GB
4 entries were displayed.				

Control and monitor I/O performance to LUNs by using Storage QoS

You can control input/output (I/O) performance to LUNs by assigning LUNs to Storage QoS policy groups. You might control I/O performance to ensure that workloads achieve specific performance objectives or to throttle a workload that negatively impacts other workloads.

About this task

Policy groups enforce a maximum throughput limit (for example, 100 MB/s). You can create a policy group without specifying a maximum throughput, which enables you to monitor performance before you control the workload.

You can also assign storage virtual machines (SVMs) with FlexVol volumes and LUNs to policy groups.

Note the following requirements about assigning a LUN to a policy group:

- The LUN must be contained by the SVM to which the policy group belongs.

You specify the SVM when you create the policy group.

- If you assign a LUN to a policy group, then you cannot assign the LUN's containing volume or SVM to a policy group.

For more information about how to use Storage QoS, see the [System administration reference](#).

Steps

1. Use the `qos policy-group create` command to create a policy group.
2. Use the `lun create` command or the `lun modify` command with the `-qos-policy-group` parameter to assign a LUN to a policy group.
3. Use the `qos statistics` commands to view performance data.
4. If necessary, use the `qos policy-group modify` command to adjust the policy group's maximum throughput limit.

Tools available to effectively monitor your LUNs

Tools are available to help you effectively monitor your LUNs and avoid running out of space.

- Active IQ Unified Manager is a free tool that enables you to manage all storage across all clusters in your environment.
- System Manager is a graphical user interface built into ONTAP that enables you to manually manage storage needs at the cluster level.
- OnCommand Insight presents a single view of your storage infrastructure and enables you to set up automatic monitoring, alerts, and reporting when your LUNs, volumes, and aggregates are running out of storage space.

Capabilities and restrictions of transitioned LUNs

In a SAN environment, a disruption in service is required during the transition of a 7-Mode volume to ONTAP. You need to shut down your hosts to complete the transition. After transition, you must update your host configurations before you can begin serving data in ONTAP.

You need to schedule a maintenance window during which you can shut down your hosts and complete the transition.

LUNs that have been transitioned from Data ONTAP operating in 7-Mode to ONTAP have certain capabilities and restrictions that affect the way the LUNs can be managed.

You can do the following with transitioned LUNs:

- View the LUN using the `lun show` command
- View the inventory of LUNs transitioned from the 7-Mode volume using the `transition 7-mode show` command
- Restore a volume from a 7-Mode Snapshot copy

Restoring the volume transitions all of the LUNs captured in the Snapshot copy

- Restore a single LUN from a 7-Mode Snapshot copy using the `snapshot restore-file` command
- Create a clone of a LUN in a 7-Mode Snapshot copy
- Restore a range of blocks from a LUN captured in a 7-Mode Snapshot copy
- Create a FlexClone of the volume using a 7-Mode Snapshot copy

You cannot do the following with transitioned LUNs:

- Access Snapshot copy-backed LUN clones captured in the volume

Related information

[Copy-based transition](#)

I/O misalignments on properly aligned LUNs overview

ONTAP might report I/O misalignments on properly aligned LUNs. In general, these misalignment warnings can be disregarded as long as you are confident that your LUN is properly provisioned and your partitioning table is correct.

LUNs and hard disks both provide storage as blocks. Because the block size for disks on the host is 512 bytes, LUNs present blocks of that size to the host while actually using larger, 4-KB blocks to store data. The 512-byte data block used by the host is referred to as a logical block. The 4-KB data block used by the LUN to store data is referred to as a physical block. This means that there are eight 512-byte logical blocks in each 4-KB physical block.

The host operating system can begin a read or write I/O operation at any logical block. I/O operations are only considered aligned when they begin at the first logical block in the physical block. If an I/O operation begins at a logical block that is not also the start of a physical block, the I/O is considered misaligned. ONTAP automatically detects the misalignment and reports it on the LUN. However, the presence of misaligned I/O does not necessarily mean that the LUN is also misaligned. It is possible for misaligned I/O to be reported on properly aligned LUNs.

If you require further investigation, see the Knowledge Base article [How to identify unaligned IO on LUNs?](#)

For more information about tools for correcting alignment problems, see the following documentation: +

- [Windows Unified Host Utilities 7.1](#)
- [Virtual Storage Console for VMware vSphere Installation and Administration Guide](#)

Achieve I/O alignment using LUN OS types

To achieve I/O alignment with your OS partitioning scheme, you should use the recommended ONTAP LUN `ostype` value that most closely matches your operating system.

The partition scheme employed by the host operating system is a major contributing factor to I/O misalignments. Some ONTAP LUN `ostype` values use a special offset known as a “prefix” to enable the default partitioning scheme used by the host operating system to be aligned.

In some circumstances, a custom partitioning table might be required to achieve I/O alignment. However, for `ostype` values with a “prefix” value greater than 0, a custom partition might create misaligned I/O.

The LUN `ostype` values in the following table should be used based on your operating system.

LUN <code>ostype</code>	Prefix (bytes)	Prefix (sectors)	Operating system
windows	32,256	63	Windows 2000, 2003 (MBR format)
windows_gpt	17,408	34	Windows 2003 (GPT format)
windows_2008	0	0	Windows 2008 and later
linux	0	0	All Linux distributions
xen	0	0	Citrix XenServer
vmware	0	0	VMware ESX
solaris	1MB	2,048	Solaris
solaris_efi	17,408	34	Solaris
hpx	0	0	HP-UX
aix	0	0	AIX

Special I/O alignment considerations for Linux

Linux distributions offer a wide variety of ways to use a LUN including as raw devices for databases, various volume managers, and file systems. It is not necessary to create partitions on a LUN when used as a raw device or as physical volume in a logical volume.

For RHEL 5 and earlier and SLES 10 and earlier, if the LUN will be used without a volume manager, you should partition the LUN to have one partition that begins at an aligned offset, which is a sector that is an even multiple of eight logical blocks.

Special I/O alignment considerations for Solaris LUNs

You need to consider various factors when determining whether you should use the `solaris` `ostype` or the `solaris_efi` `ostype`.

See the [Solaris Host Utilities Installation and Administration Guide](#) for detailed information.

ESX boot LUNs report as misaligned

LUNs used as ESX boot LUNs are typically reported by ONTAP as misaligned. ESX creates multiple partitions on the boot LUN, making it very difficult to align. Misaligned ESX boot LUNs are not typically a performance problem because the total amount of misaligned I/O is small. Assuming that the LUN was correctly provisioned with the VMware `ostype`, no action is needed.

Ways to address issues when LUNs go offline

When no space is available for writes, LUNs go offline to preserve data integrity. LUNs can run out of space and go offline for various reasons, and there are several ways you can address the issue.

If the...	You can...
Aggregate is full	<ul style="list-style-type: none">Add more disks.Use the <code>volume modify</code> command to shrink a volume that has available space.If you have space-guarantee volumes that have available space, change the volume space guarantee to <code>none</code> with the <code>volume modify</code> command.

If the...	You can...
Volume is full but there is space available in the containing aggregate	<ul style="list-style-type: none"> For space guarantee volumes, use the <code>volume modify</code> command to increase the size of your volume. For thinly provisioned volumes, use the <code>volume modify</code> command to increase the maximum size of your volume. <p>If volume autogrow is not enabled, use <code>volume modify -autogrow-mode</code> to enable it.</p> <ul style="list-style-type: none"> Delete Snapshot copies manually with the <code>volume snapshot delete</code> command, or use the <code>volume snapshot autodelete modify</code> command to automatically delete Snapshot copies.

Troubleshoot iSCSI LUNs not visible on the host

The iSCSI LUNs appear as local disks to the host. If the storage system LUNs are not available as disks on the host, you should verify the configuration settings.

Configuration setting	What to do
Cabling	Verify that the cables between the host and storage system are properly connected.
Network connectivity	<p>Verify that there is TCP/IP connectivity between the host and storage system.</p> <ul style="list-style-type: none"> From the storage system command line, ping the host interfaces that are being used for iSCSI: <pre>ping -node <i>node_name</i> -destination <i>host_ip_address_for_iSCSI</i></pre> From the host command line, ping the storage system interfaces that are being used for iSCSI: <pre>ping -node <i>node_name</i> -destination <i>host_ip_address_for_iSCSI</i></pre>

Configuration setting	What to do
System requirements	Verify that the components of your configuration are qualified. Also, verify that you have the correct host operating system (OS) service pack level, initiator version, ONTAP version, and other system requirements. The Interoperability Matrix contains the most up-to-date system requirements.
Jumbo frames	If you are using jumbo frames in your configuration, verify that jumbo frames are enabled on all devices in the network path: the host Ethernet NIC, the storage system, and any switches.
iSCSI service status	Verify that the iSCSI service is licensed and started on the storage system.
Initiator login	Verify that the initiator is logged in to the storage system. If the <code>iscsi initiator show</code> command output shows no initiators are logged in, check the initiator configuration on the host. Also verify that the storage system is configured as a target of the initiator.
iSCSI node names (IQNs)	Verify that you are using the correct initiator node names in the igroup configuration. On the host, you can use the initiator tools and commands to display the initiator node name. The initiator node names configured in the igroup and on the host must match.
LUN mappings	Verify that the LUNs are mapped to an igroup. On the storage system console, you can use one of the following commands: <ul style="list-style-type: none"> • <code>lun mapping show</code> displays all LUNs and the igroups to which they are mapped. • <code>lun mapping show -igroup</code> displays the LUNs mapped to a specific igroup.
iSCSI LIFs enable	Verify that the iSCSI logical interfaces are enabled.

Manage igroups and portsets

Ways to limit LUN access with portsets and igroups

In addition to using Selective LUN Map (SLM), you can limit access to your LUNs through igroups and portsets.

Portsets can be used with SLM to further restrict access of certain targets to certain initiators. When using SLM with portsets, LUNs will be accessible on the set of LIFs in the portset on the node that owns the LUN and on that node's HA partner.

In the following example, initiator1 does not have a portset. Without a portset, initiator1 can access LUN1 through both LIF1 and LIF2.

You can limit access to LUN1 by using a portset. In the following example, initiator1 can access LUN1 only through LIF1. However, initiator1 cannot access LUN1 through LIF2 because LIF2 is not in portset1.

Related information

- [Selective LUN Map](#)
- [Create a portset and bind to an igroup](#)

View and manage SAN initiators and igroups

You can use System Manager to view and manage initiator groups (igroups) and initiators.

About this task

- The initiator groups identify which hosts are able to access specific LUNs on the storage system.
- After an initiator and initiator groups are created, you can also edit them or delete them.
- To manage SAN initiators groups and initiators, you can perform the following tasks:
 - [View and manage SAN initiator groups](#)
 - [View and manage SAN initiators](#)

View and manage SAN initiator groups

You can use System Manager to view a list of initiator groups (igroups). From the list, you can perform additional operations.

Steps

1. In System Manager, click **Hosts > SAN Initiator Groups**.

The page displays a list of initiator groups (igroups). If the list is large, you can view additional pages of the list by clicking the page numbers at the lower right corner of the page.

The columns display various information about the igroups. Beginning with 9.11.1, the connection status of the igroup is also displayed. Hover over status alerts to view details.

2. (Optional): You can perform the following tasks by clicking the icons at the upper right corner of the list:

- **Search**

- **Download** the list.
 - **Show or Hide** columns in the list.
 - **Filter** the data in the list.
3. You can perform operations from the list:

- Click  to add an igroup.
- Click the igroup name to view the **Overview** page that shows details about the igroup.

On the **Overview** page, you can view the LUNs associated with the igroup, and you can initiate the operations to create LUNs and map the LUNs. Click **All SAN Initiators** to return to the main list.

- Hover over the igroup, then click  next to an igroup name to edit or delete the igroup.
- Hover over the area to the left of the igroup name, then check the check box. If you click **+Add to Initiator Group**, you can add that igroup to another igroup.
- In the **Storage VM** column, click the name of a storage VM to view details about it.

View and manage SAN initiators

You can use System Manager to view a list of initiators. From the list, you can perform additional operations.

Steps

1. In System Manager, click **Hosts > SAN Initiator Groups**.

The page displays a list of initiator groups (igroups).

2. To view initiators, perform the following:

- Click the **FC Initiators** tab to view a list of FC initiators.
- Click the **iSCSI Initiators** tab to view a list of iSCSI initiators.

The columns display various information about the initiators.

Beginning with 9.11.1, the connection status of the initiator is also displayed. Hover over status alerts to view details.

3. (Optional): You can perform the following tasks by clicking the icons at the upper right corner of the list:

- **Search** the list for particular initiators.
- **Download** the list.
- **Show or Hide** columns in the list.
- **Filter** the data in the list.

Create nested igroup

Beginning with ONTAP 9.9.1, you can create an igroup that consists of other existing igroups.

1. In System Manager, click **Host > SAN Initiator Groups**, and then click **Add**.
2. Enter the igroup **Name** and **Description**.

The description serves as the igroup alias.

3. Select the **Storage VM** and **Host Operating System**.

The OS type of a nested igroup cannot be changed after the igroup is created.

4. Under **Initiator Group Members** select **Existing initiator group**.

You can use **Search** to find and select the initiator groups you want to add.

Map igroups to multiple LUNs

Beginning with ONTAP 9.9.1, you can map igroups to two or more LUNs simultaneously.

1. In System Manager, click **Storage > LUNs**.
2. Select the LUNs you want to map.
3. Click **More**, then click **Map To Initiator Groups**.

The selected igroups are added to the selected LUNs. The pre-existing mappings are not overwritten.

Create a portsets and bind to an igroup

In addition to using [Selective LUN Map \(SLM\)](#), you can create a portset and bind the portset to an igroup to further limit which LIFs can be used by an initiator to access a LUN.

If you do not bind a portset to an igroup, then all of the initiators in the igroup can access mapped LUNs through all of the LIFs on the node owning the LUN and the owning node's HA partner.

What you'll need

You must have at least one LIF and one igroup.

Unless you are using interface groups, two LIFs are recommended for redundancy for both iSCSI and FC. Only one LIF is recommended for interface groups.

About this task

It is advantageous to use portsets with SLM when you have more than two LIFs on a node and you want to restrict a certain initiator to a subset of LIFs. Without portsets, all targets on the node will be accessible by all of the initiators with access to the LUN through the node owning the LUN and the owning node's HA partner.

Example 7. Steps

System Manager

Beginning with ONTAP 9.10.1, you can use System Manager to create portsets and bind them to igroups.

If you need to create a portset and bind it to an igroup in an ONTAP release earlier than 9.10.1 you must use the ONTAP CLI procedure.

1. In System Manager, click **Network > Overview > Portsets**, and click **Add**.
2. Enter the information for the new portset and click **Add**.
3. Click **Hosts > SAN Initiator Groups**.
4. To bind the portset to a new igroup, click **Add**.

To bind the portset to an existing igroup, select the igroup, click , and then click **Edit Initiator Group**.

Related information

[View and manage initiators and igroups](#)

CLI

1. Create a port set containing the appropriate LIFs:

```
portset create -vserver vserver_name -portset portset_name -protocol protocol -port-name port_name
```

If you are using FC, specify the `protocol` parameter as `fcp`. If you are using iSCSI, specify the `protocol` parameter as `iscsi`.

2. Bind the igroup to the port set:

```
lun igrup bind -vserver vserver_name -igroup igrup_name -portset portset_name
```

3. Verify that your port sets and LIFs are correct:

```
portset show -vserver vserver_name
```

Vserver	Portset	Protocol	Port Names	Igroups
vs3	portset0	iscsi	lif0,lif1	igroup1

Manage portsets

In addition to [Selective LUN Map \(SLM\)](#), you can use portsets to further limit which LIFs can be used by an initiator to access a LUN.

Beginning with ONTAP 9.10.1, you can use System Manager to change the network interfaces associated with portsets and to delete portsets.

Change network interfaces associated with a portset

1. In System Manager, select **Network > Overview > Portsets**.
2. Select the portset you want to edit then , then select **Edit Portset**.

Delete a portset

1. In System Manager, click **Network > Overview > Portsets**.
2. To delete a single portset, select the portset, select  and then select **Delete Portsets**.
To delete multiple portsets, select the portsets, and click **Delete**.

Selective LUN Map

Selective LUN Map overview

Selective LUN Map (SLM) reduces the number of paths from the host to the LUN. With SLM, when a new LUN map is created, the LUN is accessible only through paths on the node owning the LUN and its HA partner.

SLM enables management of a single igroup per host and also supports nondisruptive LUN move operations that do not require portset manipulation or LUN remapping.

Portsets can be used with SLM just as in previous versions of ONTAP to further restrict access of certain targets to certain initiators. When using SLM with portsets, LUNs will be accessible on the set of LIFs in the portset on the node that owns the LUN and on that node's HA partner.

SLM is enabled by default on all new LUN maps.

Determine whether SLM is enabled on a LUN map

If your environment has a combination of LUNs created in ONTAP and LUNs transitioned from previous versions, you might need to determine whether Selective LUN Map (SLM) is enabled on a specific LUN.

You can use the information displayed in the output of the `lun mapping show -fields reporting-nodes, node` command to determine whether SLM is enabled on your LUN map. If SLM is not enabled, "-" is displayed in the cells under the `reporting-nodes` column of the command output. If SLM is enabled, the list of nodes displayed under the `nodes` column is duplicated in the `reporting-nodes` column.

Modify the SLM reporting-nodes list

If you are moving a LUN or a volume containing LUNs to another high availability (HA) pair within the same cluster, you should modify the Selective LUN Map (SLM) reporting-nodes list before initiating the move to ensure that active, optimized LUN paths are maintained.

Steps

1. Add the destination node and its partner node to the reporting-nodes list of the aggregate or volume:

```
lun mapping add-reporting-nodes -vserver vserver_name -path lun_path -igroup
```

```
igroup_name [-destination-aggregate aggregate_name|-destination-volume  
volume_name]
```

If you have a consistent naming convention, you can modify multiple LUN mappings at the same time by using **-igroup** instead of **igroup**.

2. Rescan the host to discover the newly added paths.
3. If your OS requires it, add the new paths to your multipath network I/O (MPIO) configuration.
4. Run the command for the needed move operation and wait for the operation to finish.
5. Verify that I/O is being serviced through the Active/Optimized path:

```
lun mapping show -fields reporting-nodes
```

6. Remove the previous LUN owner and its partner node from the reporting-nodes list:

```
lun mapping remove-reporting-nodes -vserver vserver_name -path lun_path  
-igroup igroup_name -remote-nodes
```

7. Verify that the LUN has been removed from the existing LUN map:

```
lun mapping show -fields reporting-nodes
```

8. Remove any stale device entries for the host OS.
9. Change any multipathing configuration files if required.
10. Rescan the host to verify removal of old paths.
See your host documentation for specific steps to rescan your hosts.

Manage iSCSI protocol

Configure your network for best performance

Ethernet networks vary greatly in performance. You can maximize the performance of the network used for iSCSI by selecting specific configuration values.

Steps

1. Connect the host and storage ports to the same network.

It is best to connect to the same switches. Routing should never be used.

2. Select the highest speed ports available, and dedicate them to iSCSI.

10 GbE ports are best. 1 GbE ports are the minimum.

3. Disable Ethernet flow control for all ports.

You should see [Network management](#) for using the CLI to configure Ethernet port flow control.

4. Enable jumbo frames (typically MTU of 9000).

All devices in the data path, including initiators, targets, and switches, must support jumbo frames. Otherwise, enabling jumbo frames actually reduces network performance substantially.

Configure an SVM for iSCSI

To configure a storage virtual machine (SVM) for iSCSI, you must create LIFs for the SVM and assign the iSCSI protocol to those LIFs.

About this task

You need a minimum of one iSCSI LIF per node for each SVM serving data with the iSCSI protocol. For redundancy, you should create at least two LIFs per node.

Example 8. Steps

System Manager

Configure an storage VM for iSCSI with ONTAP System Manager (9.7 and later).

To configure iSCSI on a new storage VM	To configure iSCSI on an existing storage VM
<ol style="list-style-type: none">1. In System Manager, click Storage > Storage VMs and then click Add.2. Enter a name for the storage VM.3. Select iSCSI for the Access Protocol.4. Click Enable iSCSI and enter the IP address and subnet mask for the network interface. + Each node should have at least two network interfaces.5. Click Save.	<ol style="list-style-type: none">1. In System Manager, click Storage > Storage VMs.2. Click on the storage VM you want to configure.3. Click on the Settings tab, and then click  next to the iSCSI protocol.4. Click Enable iSCSI and enter the IP address and subnet mask for the network interface. + Each node should have at least two network interfaces.5. Click Save.

CLI

Configure an storage VM for iSCSI with the ONTAP CLI.

1. Enable the SVMs to listen for iSCSI traffic:

```
vserver iscsi create -vserver vserver_name -target-alias vserver_name
```

2. Create a LIF for the SVMs on each node to use for iSCSI:

- For ONTAP 9.6 and later:

```
network interface create -vserver vserver_name -lif lif_name -data  
-protocol iscsi -service-policy default-data-iscsi -home-node node_name  
-home-port port_name -address ip_address -netmask netmask
```

- For ONTAP 9.5 and earlier:

```
network interface create -vserver vserver_name -lif lif_name -role data  
-data-protocol iscsi -home-node node_name -home-port port_name -address  
ip_address -netmask netmask
```

3. Verify that you set up your LIFs correctly:

```
network interface show -vserver vserver_name
```

4. Verify that iSCSI is up and running and the target IQN for that SVM:

```
vserver iscsi show -vserver vserver_name
```

5. From your host, create iSCSI sessions to your LIFs.

Related information

Define a security policy method for an initiator

You can define a list of initiators and their authentication methods. You can also modify the default authentication method that applies to initiators that do not have a user-defined authentication method.

About this task

You can generate unique passwords using security policy algorithms in the product or you can manually specify the passwords that you want to use.

Not all initiators support hexadecimal CHAP secret passwords.

Steps

1. Use the vserver iscsi security create command to create a security policy method for an initiator.

```
vserver iscsi security create -vserver vs2 -initiator iqn.1991-05.com.microsoft:host1 -auth-type CHAP -user-name bob1 -outbound-user-name bob2
```

2. Follow the screen commands to add the passwords.

Creates a security policy method for initiator iqn.1991-05.com.microsoft:host1 with inbound and outbound CHAP user names and passwords.

Delete an iSCSI service for an SVM

You can delete an iSCSI service for a storage virtual machine (SVM) if it is no longer required.

What you'll need

The administration status of the iSCSI service must be in the “down” state before you can delete an iSCSI service. You can move the administration status to down with the vserver iscsi modify command.

Steps

1. Use the vserver iscsi modify command to stop the I/O to the LUN.

```
vserver iscsi modify -vserver vs1 -status-admin down
```

2. Use the vserver iscsi delete command to remove the iscsi service from the SVM.

```
vserver iscsi delete -vserver vs_1
```

3. Use the vserver iscsi show command to verify that you deleted the iSCSI service from the SVM.

```
vserver iscsi show -vserver vs1
```

Get more details in iSCSI session error recoveries

Increasing the iSCSI session error recovery level enables you to receive more detailed information about iSCSI error recoveries. Using a higher error recovery level might cause a minor reduction in iSCSI session performance.

About this task

By default, ONTAP is configured to use error recovery level 0 for iSCSI sessions. If you are using an initiator that has been qualified for error recovery level 1 or 2, you can choose to increase the error recovery level. The modified session error recovery level affects only the newly created sessions and does not affect existing sessions.

Beginning with ONTAP 9.4, the `max-error-recovery-level` option is not supported in the `iscsi show` and `iscsi modify` commands.

Steps

1. Enter advanced mode:

```
set -privilege advanced
```

2. Verify the current setting by using the `iscsi show` command.

```
iscsi show -vserver vs3 -fields max-error-recovery-level
```

```
vserver max-error-recovery-level  
-----  
vs3      0
```

3. Change the error recovery level by using the `iscsi modify` command.

```
iscsi modify -vserver vs3 -max-error-recovery-level 2
```

Register the SVM with an iSNS server

You can use the `vserver iscsi isns` command to configure the storage virtual machine (SVM) to register with an iSNS server.

About this task

The `vserver iscsi isns create` command configures the SVM to register with the iSNS server. The SVM does not provide commands that enable you to configure or manage the iSNS server. To manage the iSNS server, you can use the server administration tools or the interface provided by the vendor for the iSNS server.

Steps

1. On your iSNS server, ensure that your iSNS service is up and available for service.
2. Create the SVM management LIF on a data port:

```
network interface create -vserver SVM_name -lif lif_name -role data -data  
-protocol none -home-node home_node_name -home-port home_port -address  
IP_address -netmask network_mask
```

3. Create an iSCSI service on your SVM if one does not already exist:

```
vserver iscsi create -vserver SVM_name
```

4. Verify that the iSCSI service was created successfully:

```
iscsi show -vserver SVM_name
```

5. Verify that a default route exists for the SVM:

```
network route show -vserver SVM_name
```

6. If a default route does not exist for the SVM, create a default route:

```
network route create -vserver SVM_name -destination destination -gateway  
gateway
```

7. Configure the SVM to register with the iSNS service:

```
vserver iscsi isns create -vserver SVM_name -address IP_address
```

Both IPv4 and IPv6 address families are supported. The address family of the iSNS server must be the same as that of the SVM management LIF.

For example, you cannot connect anSVM management LIF with an IPv4 address to an iSNS server with an IPv6 address.

8. Verify that the iSNS service is running:

```
vserver iscsi isns show -vserver SVM_name
```

9. If the iSNS service is not running, start it:

```
vserver iscsi isns start -vserver SVM_name
```

Resolve iSCSI error messages on the storage system

There are a number of common iSCSI-related error messages that you can view with the event log show command. You need to know what these messages mean and what you can do to resolve the issues they identify.

The following table contains the most common error messages, and instructions for resolving them:

Message	Explanation	What to do
iSCSI: network interface identifier disabled for use; incoming connection discarded	The iSCSI service is not enabled on the interface.	<p>You can use the <code>iscsi interface enable</code> command to enable the iSCSI service on the interface. For example:</p> <pre>iscsi interface enable -vserver vs1 -lif lif1</pre>
iSCSI: Authentication failed for initiator nodename	CHAP is not configured correctly for the specified initiator.	<p>You should check the CHAP settings; you cannot use the same user name and password for inbound and outbound settings on the storage system:</p> <ul style="list-style-type: none"> • Inbound credentials on the storage system must match outbound credentials on the initiator. • Outbound credentials on the storage system must match inbound credentials on the initiator.

iSCSI LIF failover for ASA platforms

Beginning with ONTAP 9.11.1 on All SAN Array (ASA) platforms, the iSCSI LIF failover feature supports automatic and manual migration of iSCSI LIFs in an SFO partner failover (when an iSCSI LIF moves from its home node/port to its HA partner node/port and back again) and in a local failover (when an iSCSI LIF moves from its unhealthy port to a healthy port on its current home node and back again). This feature provides faster I/O resumption for SAN workloads running on iSCSI.

About enabling iSCSI LIF failover

You should familiarize yourself with aspects of when iSCSI LIF failover is automatically enabled and when you must manually enable it, including how newly created iSCSI LIFs and existing iSCSI LIFs are affected.

- The automatic migration of an iSCSI LIF is a LIF failover and auto-revert, which is triggered in certain events, such as planned or unplanned failover, a physical ethernet link down, or a node dropping out of replicated database (RDB) quorum.
 - After upgrading your ASA HA pair to ONTAP 9.11.1, this feature is automatically enabled on newly created iSCSI LIFs if no iSCSI LIFs exist in the specified storage VM or if all existing iSCSI LIFs in the specified storage VM are already enabled with iSCSI LIF failover.
 - For iSCSI LIFs created prior to upgrading to ONTAP 9.11.1, to use the iSCSI LIF failover feature, you must enable it using the ONTAP CLI. (Enabling the failover feature and auto-revert capability means changing the failover policy to `sfo-partner-only` and designating the auto-revert value to `true`.)

[Manage iSCSI LIFs using the ONTAP CLI](#)

If you do not enable iSCSI LIF failover on the existing iSCSI LIFs, when there is a failover event, the iSCSI LIFs will not failover.

Additionally, if after upgrading to ONTAP 9.11.1 or later you have existing iSCSI LIFs in a storage VM that have not been enabled with the iSCSI LIF failover feature and you create new iSCSI LIFs in the same storage VM, the new iSCSI LIFs assume the same failover policy (disabled) of the existing iSCSI LIFs in the storage VM.

- The manual migration of an iSCSI LIF is a LIF migrate and revert, which is initiated by the cluster admin using the ONTAP CLI or System Manager.

Migrate and revert an iSCSI LIF

You manually migrate and revert an iSCSI LIF under the following circumstances:

- When scheduled maintenance or replacement is needed.
- When you have a pre-existing iSCSI LIF, meaning that the iSCSI LIF was created before you upgraded your HA pair to ONTAP 9.11.1 or later, and you have not enabled the iSCSI LIF failover feature on the LIF.

How iSCSI LIF failover works

For LIFs with iSCSI LIF failover enabled (either automatically or manually), the following applies.

- For LIFs using the `data-iscsi` service policy, the failover-policy is restricted to `sfo-partner-only`, `local-only`, and `disabled`.
- iSCSI LIFs can failover only to the HA partner when their failover policy is set to `sfo-partner-only`.
- Auto-revert of LIFs happens when the auto-revert is set to `true` and when the LIF's home port is healthy and able to host the LIF.
- On a planned or unplanned node takeover, the iSCSI LIF on the node which is taken-over fails over to the HA partner. The port on which the LIF fails over is determined by VIF Manager.
- Once the failover is complete, the iSCSI LIF operates normally.
- When a giveback is initiated, the iSCSI LIF reverts back to its home node and port, if auto-revert is set to `true`.
- When an ethernet link goes down on a port hosting one or more iSCSI LIFs, VIF Manager migrates the LIFs from the down port to a different port in the same broadcast domain. The new port could be in the same node or its HA partner. Once the link is restored and if auto-revert is set to `true`, VIF Manager reverts the iSCSI LIFs back to their home node and home port.
- When a node drops out of replicated database (RDB) quorum, VIF Manager migrates the iSCSI LIFs from the out of quorum node to its HA partner. Once the node comes back into quorum and if auto-revert is set to `true`, VIF Manager reverts the iSCSI LIFs back to their home node and home port.

Migrate and revert an iSCSI LIF

You can use System Manager or the ONTAP CLI to manually migrate an iSCSI LIF to a different port on the same node or to a different port on the HA partner, and then revert the LIF back to its home node and home port.

Migrate and revert an iSCSI LIF using System Manager

You can use System Manager to manually migrate and revert one or more iSCSI LIFs (network interfaces) to another port on the same node or to a port on the HA partner.

Before you begin

You must have an ASA platform HA pair and it must be running ONTAP 9.11.1 or later.

Migrate a LIF

Steps

1. In System Manager, click **Network > Overview > Network Interfaces**
2. Select the LIF you want to migrate, click , and then click **Migrate**.
3. In the **Migrate Interface** dialog box, select the destination node and port of the HA partner.

You have the option of permanently migrating the iSCSI LIF by checking the checkbox. Understand that the iSCSI LIF must be offline before it is permanently migrated. Additionally, once an iSCSI LIF is permanently migrated, it cannot be undone. There is no revert option.

4. Click **Migrate**.

Revert a LIF

Steps

1. In System Manager, click **Network > Overview > Network Interfaces**.
2. Select the LIF you want to revert, click  and then click **Revert Network Interface**.
3. In the **Revert Network Interface** dialog box, click **Revert**.

Migrate and revert an iSCSI LIF using the ONTAP CLI

You can use the ONTAP CLI to manually migrate and revert one or more iSCSI LIFs to another port on the same node or to a port on the HA partner.

Before you begin

You must have an ASA platform HA pair and it must be running ONTAP 9.11.1 or later.

If you want to...	Use this command...
Migrate an iSCSI LIF to another node/port	See Migrate a LIF for the available commands.
Revert an iSCSI LIF back to its home node/port	See Revert a LIF to its home port for the available commands.

Manage iSCSI LIFs using the ONTAP CLI

You can use the ONTAP CLI to manage iSCSI LIFs, including creating new iSCSI LIFs and enabling the iSCSI LIF failover feature for pre-existing LIFs.

Before you Begin

You must have an ASA platform HA pair and it must be running ONTAP 9.11.1 or later.

About this task

See the [ONTAP Command Reference](#) for a full list of network interface commands.

If you want to...	Use this command...
Create an iSCSI LIF	<pre>network interface create -vserver SVM_name -lif iscsi_lif -service-policy default-data-blocks -data-protocol iscsi -home-node node_name -home-port port_name -address IP_address -netmask netmask_value</pre> <p>If needed, see Create a LIF for more information.</p>
Verify that the LIF was created successfully	<pre>network interface show -vserver SVM_name -fields failover-policy,failover- group,auto-revert,is-home</pre>
Verify if you can override the auto-revert default on iSCSI LIFs	<pre>network interface modify -vserver SVM_name -lif iscsi_lif -auto-revert false</pre>
Perform a storage failover on an iSCSI LIF	<pre>storage failover takeover -ofnode node_name -option normal</pre> <p>You receive a warning: A takeover will be initiated. Once the partner node reboots, a giveback will be automatically initiated. Do you want to continue? {y/n}:</p> <p>A y response displays a takeover message from its HA partner.</p>
Enable iSCSI LIF failover feature for pre-existing LIFs	<p>For iSCSI LIFs created before you upgraded your cluster to ONTAP 9.11.1 or later, you can enable the iSCSI LIF failover feature (by modifying the failover policy to sfo-partner-only and by modifying the auto-revert capability to true):</p> <pre>network interface modify -vserver SVM_name -lif iscsi_lif -failover-policy sfo-partner-only -auto-revert true</pre> <p>This command can be run on all the iSCSI LIFs in a Storage VM by specifying “-lif*” and keeping all other parameters the same.</p>

Disable iSCSI LIF failover feature for pre-existing LIFs	<p>For iSCSI LIFs created before you upgraded your cluster to ONTAP 9.11.1 or later, you can disable the iSCSI LIF failover feature and the auto-revert capability:</p> <pre>network interface modify -vserver <i>SVM_name</i> -lif <i>iscsi_lif</i> -failover-policy disabled -auto-revert false</pre> <p>This command can be run on all the iSCSI LIFs in a storage VM by specifying “-lif*” and keeping all other parameters the same.</p>
--	---

Manage FC protocol

Configure an SVM for FC

To configure a storage virtual machine (SVM) for FC, you must create LIFs for the SVM and assign the FC protocol to those LIFs.

Before you begin

You must have an FC license and it must be enabled. If the FC license is not enabled, the LIFs and SVMs appear to be online but the operational status is down. The FC service must be enabled for your LIFs and SVMs to be operational. You must use single initiator zoning for all of the FC LIFs in the SVM to host the initiators.

About this task

NetApp supports a minimum of one FC LIF per node for each SVM serving data with the FC protocol. You must use two LIFs per node and two fabrics, with one LIF per node attached. This provides for redundancy at the node layer and the fabric.

Example 9. Steps

System Manager

Configure an storage VM for iSCSI with ONTAP System Manager (9.7 and later).

To configure FC on a new storage VM	To configure FC on an existing storage VM
<ol style="list-style-type: none">1. In System Manager, click Storage > Storage VMs and then click Add.2. Enter a name for the storage VM.3. Select FC for the Access Protocol.4. Click Enable FC. + The FC ports are automatically assigned.5. Click Save.	<ol style="list-style-type: none">1. In System Manager, click Storage > Storage VMs.2. Click on the storage VM you want to configure.3. Click on the Settings tab, and then click  next to the FC protocol.4. Click Enable FC and enter the IP address and subnet mask for the network interface. + The FC ports are automatically assigned.5. Click Save.

CLI

1. Enable FC service on the SVM:

```
vserver fcp create -vserver vserver_name -status-admin up
```

2. Create two LIFs for the SVMs on each node serving FC:

- For ONTAP 9.6 and later:

```
network interface create -vserver vserver_name -lif lif_name -data  
-protocol fcp -service-policy default-data-fcp -home-node node_name  
-home-port port_name -address ip_address -netmask netmask
```

- For ONTAP 9.5 and earlier:

```
network interface create -vserver vserver_name -lif lif_name -role data  
-data-protocol fcp -home-node node_name -home-port port
```

3. Verify that your LIFs have been created and that their operational status is online:

```
network interface show -vserver vserver_name lif_name
```

[NetApp Interoperability Matrix Tool](#)

[Considerations for LIFs in cluster SAN environments](#)

Delete an FC service for an SVM

You can delete an FC service for a storage virtual machine (SVM) if it is no longer

required.

What you'll need

The administration status must be “down” before you can delete a FC service for an SVM. You can set the administration status to down with either the `vserver fcp modify` command or the `vserver fcp stop` command.

Steps

1. Use the `vserver fcp stop` command to stop the I/O to the LUN.

```
vserver fcp stop -vserver vs_1
```

2. Use the `vserver fcp delete` command to remove the service from the SVM.

```
vserver fcp delete -vserver vs_1
```

3. Use the `vserver fcp show` to verify that you deleted the FC service from your SVM:

```
vserver fcp show -vserver vs_1
```

Recommended MTU configurations for FCoE jumbo frames

For Fibre Channel over Ethernet (FCoE), jumbo frames for the Ethernet adapter portion of the CNA should be configured at 9000 MTU. Jumbo frames for the FCoE adapter portion of the CNA should be configured at greater than 1500 MTU. Only configure jumbo frames if the initiator, target, and all intervening switches support and are configured for jumbo frames.

Manage NVMe protocol

Start the NVMe service for an SVM

Before you can use the NVMe protocol on your storage virtual machine (SVM), you must start the NVMe service on the SVM.

Before you begin

NVMe must be allowed as a protocol on your system.

The following NVMe protocols are supported:

Protocol	Beginning with ...	Allowed by...
TCP	ONTAP 9.10.1	Default
FCP	ONTAP 9.4	Default

Steps

1. Change the privilege setting to advanced:

```
set -privilege advanced
```

2. Verify that NVMe is allowed as a protocol:

```
vserver nvme show
```

3. Create the NVMe protocol service:

```
vserver nvme create
```

4. Start the NVMe protocol service on the SVM:

```
vserver nvme modify -status -admin up
```

Delete NVMe service from an SVM

If needed, you can delete the NVMe service from your storage virtual machine (SVM).

Steps

1. Change the privilege setting to advanced:

```
set -privilege advanced
```

2. Stop the NVMe service on the SVM:

```
vserver nvme modify -status -admin down
```

3. Delete the NVMe service:

```
vserver nvme delete
```

Resize a namespace

Beginning with ONTAP 9.10.1, you can use the ONTAP CLI to increase or decrease the size of a NVMe namespace. You can use System Manager to increase the size of a NVMe namespace.

Increase the size of a namespace

System Manager

1. Click **Storage > NVMe Namespaces**.
2. Hoover over the namespace you want to increase, click  , and then click **Edit**.
3. Under **CAPACITY**, change the size of the namespace.

CLI

1. Enter the following command: `vserver nvme namespace modify -vserver SVM_name -path path -size new_size_of_namespace`

Decrease the size of a namespace

You must use the ONTAP CLI to decrease the size of a NVMe namespace.

1. Change the privilege setting to advanced:

```
set -privilege advanced
```

2. Decrease the size of the namespace:

```
vserver nvme namespace modify -vserver SVM_name -path namespace_path -size new_size_of_namespace
```

Convert a namespace into a LUN

Beginning with ONTAP 9.11.1, you can use the ONTAP CLI to in-place convert an existing NVMe namespace to a LUN.

Before you start

- Specified NVMe namespace should not have any existing maps to a Subsystem.
- Namespace should not be part of a snapshot or on the destination side of SnapMirror relationship as a read-only namespace.
- Since NVMe namespaces are only supported with specific platforms and network cards, this feature only works with specific hardware.

Steps

1. You enter the following command to convert an NVMe namespace to a LUN:

```
lun convert-from-namespace -vserver -namespace-path
```

Set up secure authentication over NVMe/TCP

Beginning with ONTAP 9.12.1 secure, bidirectional and unidirectional authentication between an NVMe host and controller is supported over NVME/TCP using the DH-HMAC-CHAP authentication protocol.

To set up secure authentication, each host or controller must be associated with a DH-HMAC-CHAP key which is a combination of the NQN of the NVMe host or controller and an authentication secret configured by the administrator. In order for an NVMe host or controller to authenticate its peer, it must know the key associated with the peer. SHA-256 is the default hash function and 2048-bit is the default DH group.

Steps

1. Add DH-HMAC-CHAP authentication to your NVMe subsystem:

```
vserver nvme subsystem host add -vserver svm_name -subsystem subsystem -host -nqn host_nqn -dhchap-host-secret authentication_host_secret -dhchap-controller-secret authentication_controller_secret -dhchap-hash-function {sha-256|sha-512} -dhchap-group {none|2048-bit|3072-bit|4096-bit|6144-bit|8192-bit}
```

2. Verify that the DH-HMAC CHAP authentication protocol is added to your host:

```
vserver nvme subsystem host show
```

```
[ -dhchap-hash-function {sha-256|sha-512} ] Authentication Hash Function  
[ -dhchap-group {none|2048-bit|3072-bit|4096-bit|6144-bit|8192-bit} ] Authentication Diffie-Hellman Group  
[ -dhchap-mode {none|unidirectional|bidirectional} ] Authentication Mode
```

3. Verify that the DH-HMAC CHAP authentication was performed during NVMe controller creation:

```
vserver nvme subsystem controller show
```

```
[ -dhchap-hash-function {sha-256|sha-512} ] Authentication Hash Function  
[ -dhchap-group {none|2048-bit|3072-bit|4096-bit|6144-bit|8192-bit} ] Authentication Diffie-Hellman Group  
[ -dhchap-mode {none|unidirectional|bidirectional} ] Authentication Mode
```

Disable secure authentication over NVMe/TCP

If you are running the NVMe/TCP protocol and you have established secure authentication using DH-HMAC-CHAP, you can choose to disable it at any time.

However, if you are reverting from ONTAP 9.12.1 or later to ONTAP 9.12.0 or earlier you must disable secure authentication before you revert. If secure authentication using DH-HMAC-CHAP is not disabled, revert will fail.

Steps

1. Remove the host from the subsystem to disable DH-HMAC-CHAP authentication:

```
vserver nvme subsystem host remove -vserver svm_name -subsystem subsystem -host-nqn host_nqn
```

2. Verify that the DH-HMAC-CHAP authentication protocol is removed from the host:

```
vserver nvme subsystem host show
```

3. Add the host back to the subsystem without authentication:

```
vserver nvme subsystem host add -vserver svm_name -subsystem subsystem -host
```

```
-nqn host_nqn
```

Manage systems with FC adapters

Manage systems with FC adapters

Commands are available to manage onboard FC adapters and FC adapter cards. These commands can be used to configure the adapter mode, display adapter information, and change the speed.

Most storage systems have onboard FC adapters that can be configured as initiators or targets. You can also use FC adapter cards configured as initiators or targets. Initiators connect to back-end disk shelves, and possibly foreign storage arrays (FlexArray). Targets connect only to FC switches. Both the FC target HBA ports and the switch port speed should be set to the same value and should not be set to auto.

Related information

[SAN configuration](#)

Commands for managing FC adapters

You can use FC commands to manage FC target adapters, FC initiator adapters, and onboard FC adapters for your storage controller. The same commands are used to manage FC adapters for the FC protocol and the FC-NVMe protocol.

FC initiator adapter commands work only at the node level. You must use the `run -node node_name` command before you can use the FC initiator adapter commands.

Commands for managing FC target adapters

If you want to...	Use this command...
Display FC adapter information on a node	<code>network fcp adapter show</code>
Modify FC target adapter parameters	<code>network fcp adapter modify</code>
Display FC protocol traffic information	<code>run -node node_name sysstat -f</code>
Display how long the FC protocol has been running	<code>run -node node_name uptime</code>
Display adapter configuration and status	<code>run -node node_name sysconfig -v adapter</code>
Verify which expansion cards are installed and whether there are any configuration errors	<code>run -node node_name sysconfig -ac</code>
View a man page for a command	<code>man command_name</code>

Commands for managing FC initiator adapters

If you want to...	Use this command...
Display information for all initiators and their adapters in a node	run -node <i>node_name</i> storage show adapter
Display adapter configuration and status	run -node <i>node_name</i> sysconfig -v adapter
Verify which expansion cards are installed and whether there are any configuration errors	run -node <i>node_name</i> sysconfig -ac

Commands for managing onboard FC adapters

If you want to...	Use this command...
Display the status of the onboard FC ports	run -node <i>node_name</i> system hardware unified-connect show

Configure FC adapters

Each onboard FC port can be individually configured as an initiator or a target. Ports on certain FC adapters can also be individually configured as either a target port or an initiator port, just like the onboard FC ports. A list of adapters that can be configured for target mode is available in the [NetApp Hardware Universe](#).

Target mode is used to connect the ports to FC initiators. Initiator mode is used to connect the ports to tape drives, tape libraries, or third-party storage with FlexArray Virtualization or Foreign LUN Import (FLI).

The same steps are used when configuring FC adapters for the FC protocol and the FC-NVMe protocol. However, only certain FC adapters support FC-NVMe. See the [NetApp Hardware Universe](#) for a list of adapters that support the FC-NVMe protocol.

Configure FC adapters for target mode

Steps

1. Take the adapter offline:

```
node run -node node_name storage disable adapter adapter_name
```

If the adapter does not go offline, you can also remove the cable from the appropriate adapter port on the system.

2. Change the adapter from initiator to target:

```
system hardware unified-connect modify -t target -node node_name adapter adapter_name
```

3. Reboot the node hosting the adapter you changed.

4. Verify that the target port has the correct configuration:

```
network fcp adapter show -node node_name
```

5. Bring your adapter online:

```
network fcp adapter modify -node node_name -adapter adapter_port -state up
```

Configure FC adapters for initiator mode

What you'll need

- LIFs on the adapter must be removed from any port sets of which they are members.
- All LIF's from every storage virtual machine (SVM) using the physical port to be modified must be migrated or destroyed before changing the personality of the physical port from target to initiator.

NVMe/FC does support initiator mode.

Steps

1. Remove all LIFs from the adapter:

```
network interface delete -vserver SVM_name -lif LIF_name,LIF_name
```

2. Take your adapter offline:

```
network fcp adapter modify -node node_name -adapter adapter_port -status-admin down
```

If the adapter does not go offline, you can also remove the cable from the appropriate adapter port on the system.

3. Change the adapter from target to initiator:

```
system hardware unified-connect modify -t initiator adapter_port
```

4. Reboot the node hosting the adapter you changed.

5. Verify that the FC ports are configured in the correct state for your configuration:

```
system hardware unified-connect show
```

6. Bring the adapter back online:

```
node run -node node_name storage enable adapter adapter_port
```

View adapter settings

You can use specific commands to view information about your FC/UTA adapters.

FC target adapter

Step

1. Use the `network fcp adapter show` command to display adapter information: `network fcp`

```
adapter show -instance -node node1 -adapter 0a
```

The output displays system configuration information and adapter information for each slot that is used.

Unified Target Adapter (UTA) X1143A-R6

Steps

1. Boot your controller without the cables attached.
2. Run the system hardware unified-connect show command to see the port configuration and modules.
3. View the port information before configuring the CNA and ports.

Change the UTA2 port from CNA mode to FC mode

You should change the UTA2 port from Converged Network Adapter (CNA) mode to Fibre Channel (FC) mode to support the FC initiator and FC target mode. You should change the personality from CNA mode to FC mode when you need to change the physical medium that connects the port to its network.

Steps

1. Take the adapter offline:

```
network fcp adapter modify -node node_name -adapter adapter_name -status-admin down
```

2. Change the port mode:

```
ucadmin modify -node node_name -adapter adapter_name -mode fcp
```

3. Reboot the node, and then bring the adapter online:

```
network fcp adapter modify -node node_name -adapter adapter_name -status-admin up
```

4. Notify your admin or VIF manager to delete or remove the port, as applicable:

- If the port is used as a home port of a LIF, is a member of an interface group (ifgrp), or hosts VLANs, then an admin should do the following:
 - i. Move the LIFs, remove the port from the ifgrp, or delete the VLANs, respectively.
 - ii. Manually delete the port by running the network port delete command.

If the network port delete command fails, the admin should address the errors, and then run the command again.

- If the port is not used as the home port of a LIF, is not a member of an ifgrp, and does not host VLANs, then the VIF manager should remove the port from its records at the time of reboot.

If the VIF manager does not remove the port, then the admin must remove it manually after the reboot by using the network port delete command.

```
net-f8040-34::> network port show
```

```

```
net-f8040-34::> ucadmin modify local 0e fc
```

Warning: Mode on adapter 0e and also adapter 0f will be changed to fc.

Do you want to continue? {y|n}: y

Any changes will take effect after rebooting the system. Use the "system node reboot" command to reboot.

```
net-f8040-34::> reboot local
```

(system node reboot)

Warning: Are you sure you want to reboot node "net-f8040-34-01"?

{y|n}: y

5. Verify that you have the correct SFP+ installed:

```
network fcp adapter show -instance -node -adapter
```

For CNA, you should use a 10Gb Ethernet SFP. For FC, you should either use an 8 Gb SFP or a 16 Gb SFP, before changing the configuration on the node.

Change the CNA/UTA2 target adapter optical modules

You should change the optical modules on the unified target adapter (CNA/UTA2) to support the personality mode you have selected for the adapter.

Steps

1. Verify the current SFP+ used in the card. Then, replace the current SFP+ with the appropriate SFP+ for the preferred personality (FC or CNA).
2. Remove the current optical modules from the X1143A-R6 adapter.
3. Insert the correct modules for your preferred personality mode (FC or CNA) optics.
4. Verify that you have the correct SFP+ installed:

```
network fcp adapter show -instance -node -adapter
```

Supported SFP+ modules and Cisco-branded Copper (Twinax) cables are listed in the *Hardware Universe*.

Related information

[NetApp Hardware Universe](#)

Supported port configurations for X1143A-R6 adapters

The FC target mode is the default configuration for X1143A-R6 adapter ports. However, ports on this adapter can be configured as either 10-Gb Ethernet and FCoE ports or as 16-Gb FC ports.

When configured for Ethernet and FCoE, X1143A-R6 adapters support concurrent NIC and FCoE target traffic on the same 10-GBE port. When configured for FC, each two-port pair that shares the same ASIC can be

individually configured for FC target or FC initiator mode. This means that a single X1143A-R6 adapter can support FC target mode on one two-port pair and FC initiator mode on another two-port pair.

Related information

[NetApp Hardware Universe](#)

[SAN configuration](#)

Configure the ports

To configure the unified target adapter (X1143A-R6), you must configure the two adjacent ports on the same chip in the same personality mode.

Steps

1. Configure the ports as needed for Fibre Channel (FC) or Converged Network Adapter (CNA) using the system node hardware unified-connect modify command.
2. Attach the appropriate cables for FC or 10 Gb Ethernet.
3. Verify that you have the correct SFP+ installed:

```
network fcp adapter show -instance -node -adapter
```

For CNA, you should use a 10Gb Ethernet SFP. For FC, you should either use an 8 Gb SFP or a 16 Gb SFP, based on the FC fabric being connected to.

Prevent loss of connectivity when using the X1133A-R6 adapter

You can prevent loss of connectivity during a port failure by configuring your system with redundant paths to separate X1133A-R6 HBAs.

The X1133A-R6 HBA is a 4-port, 16 Gb FC adapter consisting of two 2-port pairs. The X1133A-R6 adapter can be configured as target mode or initiator mode. Each 2-port pair is supported by a single ASIC (for example, Port 1 and Port 2 on ASIC 1 and Port 3 and Port 4 on ASIC 2). Both ports on a single ASIC must be configured to operate in the same mode, either target mode or initiator mode. If an error occurs with the ASIC supporting a pair, both ports in the pair go offline.

To prevent this loss of connectivity, you configure your system with redundant paths to separate X1133A-R6 HBAs, or with redundant paths to ports supported by different ASICs on the HBA.

Manage LIFs for all SAN protocols

Manage LIFs for all SAN protocols

LIFs are connected to the SAN hosts. They can be removed from port sets, moved to different nodes within a storage virtual machine (SVM), and deleted.

Related information

[Network management](#)

Configure an NVMe LIF

Certain requirements must be met when configuring NVMe LIFs.

What you'll need

NVMe must be supported by the FC adapter on which you create the LIF. Supported adapters are listed in the [Hardware Universe](#).

NetApp Hardware Universe

About this task

The following rules apply when creating an NVMe LIF:

- NVMe can be the only data protocol on data LIFs.
- You should configure one management LIF for every SVM that supports SAN.
- For ONTAP 9.5 and later:
 - You can only configure two NVMe LIFs per node on a maximum of four nodes.
 - You must configure an NVMe LIF on the node containing the namespace and on node's HA partner.
- For ONTAP 9.4 only:
 - NVMe LIFs and namespaces must be hosted on the same node.
 - Only one NVMe data LIF can be configured per SVM.

Steps

1. Create the LIF:

```
network interface create -vserver SVM_name -lif LIF_name -role LIF_role -data  
-protocol fc-nvme -home-node home_node -home-port  
home_port
```

2. Verify that the LIF was created:

```
network interface show -vserver SVM_name
```

What to know before moving a SAN LIF

You only need to perform a LIF movement if you are changing the contents of your cluster, for example, adding nodes to the cluster or deleting nodes from the cluster. If you perform a LIF movement, you do not have to re-zone your FC fabric or create new iSCSI sessions between the attached hosts of your cluster and the new target interface.

You cannot move a SAN LIF using the `network interface move` command. SAN LIF movement must be performed by taking the LIF offline, moving the LIF to a different home node or port, and then bringing it back online in its new location. Asymmetric Logical Unit Access (ALUA) provides redundant paths and automatic path selection as part of any ONTAP SAN solution. Therefore, there is no I/O interruption when the LIF is taken offline for the movement. The host simply retries and then moves I/O to another LIF.

Using LIF movement, you can nondisruptively do the following:

- Replace one HA pair of a cluster with an upgraded HA pair in a way that is transparent to hosts accessing LUN data
- Upgrade a target interface card
- Shift the resources of a storage virtual machine (SVM) from one set of nodes in a cluster to another set of nodes in the cluster

Remove a SAN LIF from a port set

If the LIF you want to delete or move is in a port set, you must remove the LIF from the port set before you can delete or move the LIF.

About this task

You need to do Step 1 in the following procedure only if one LIF is in the port set. You cannot remove the last LIF in a port set if the port set is bound to an initiator group. Otherwise, you can start with Step 2 if multiple LIFs are in the port set.

Steps

1. If only one LIF is in the port set, use the `lun igrup unbind` command to unbind the port set from the initiator group.

When you unbind an initiator group from a port set, all of the initiators in the initiator group have access to all target LUNs mapped to the initiator group on all network interfaces.

```
cluster1::>lun igrup unbind -vserver vs1 -igroup ig1
```

2. Use the `lun portset remove` command to remove the LIF from the port set.

```
cluster1::> port set remove -vserver vs1 -portset ps1 -port-name lif1
```

Move a SAN LIF

If a node needs to be taken offline, you can move a SAN LIF to preserve its configuration information, such as its WWPN, and avoid rezoning the switch fabric. Because a SAN LIF must be taken offline before it is moved, host traffic must rely on host multipathing software to provide nondisruptive access to the LUN. You can move SAN LIFs to any node in a cluster, but you cannot move the SAN LIFs between storage virtual machines (SVMs).

What you'll need

If the LIF is a member of a port set, the LIF must have been removed from the port set before the LIF can be moved to a different node.

About this task

The destination node and physical port for a LIF that you want to move must be on the same FC fabric or Ethernet network. If you move a LIF to a different fabric that has not been properly zoned, or if you move a LIF to an Ethernet network that does not have connectivity between iSCSI initiator and target, the LUN will be inaccessible when you bring it back online.

Steps

1. View the administrative and operational status of the LIF:

```
network interface show -vserver vserver_name
```

2. Change the status of the LIF to down (offline):

```
network interface modify -vserver vserver_name -lif LIF_name -status-admin  
down
```

3. Assign the LIF a new node and port:

```
network interface modify -vserver vserver_name -lif LIF_name -home-node  
node_name -home-port port_name
```

4. Change the status of the LIF to up (online):

```
network interface modify -vserver vserver_name -lif LIF_name -status-admin up
```

5. Verify your changes:

```
network interface show -vserver vserver_name
```

Delete a LIF in a SAN environment

Before you delete a LIF, you should ensure that the host connected to the LIF can access the LUNs through another path.

What you'll need

If the LIF you want to delete is a member of a port set, you must first remove the LIF from the port set before you can delete the LIF.

System Manager

Delete a LIF with ONTAP System Manager (9.7 and later).

Steps

1. In System Manager, click **Network > Overview**, and then select **Network Interfaces**.
2. Select the storage VM from which you want to delete the LIF.
3. Click  and select **Delete**.

CLI

Delete a LIF with the ONTAP CLI.

Steps

1. Verify the name of the LIF and current port to be deleted:

```
network interface show -vserver vserver_name
```

2. Delete the LIF:

```
network interface delete
```

```
network interface delete -vserver vs1 -lif lif1
```

3. Verify that you deleted the LIF:

```
network interface show
```

```
network interface show -vserver vs1
```

Logical Vserver Home	Status Interface	Network Admin/Oper	Address/Mask	Current Node	Current Port	Is
vs1	true	lif2	up/up	192.168.2.72/24	node-01	e0b
	true	lif3	up/up	192.168.2.73/24	node-01	e0b

SAN LIF requirements for adding nodes to a cluster

You need to be aware of certain considerations when adding nodes to a cluster.

- You must create LIFs on the new nodes as appropriate before you create LUNs on those new nodes.
- You must discover those LIFs from the hosts as dictated by the host stack and protocol.

- You must create LIFs on the new nodes so that the LUN and volume movements are possible without using the cluster interconnect network.

Configure iSCSI LIFs to return FQDN to host iSCSI SendTargets Discovery Operation

Beginning with ONTAP 9, iSCSI LIFs can be configured to return a Fully Qualified Domain Name (FQDN) when a host OS sends an iSCSI SendTargets Discovery Operation. Returning a FQDN is useful when there is a Network Address Translation (NAT) device between the host OS and the storage service.

About this task

IP addresses on one side of the NAT device are meaningless on the other side, but FQDNs can have meaning on both sides.

The FQDN value interoperability limit is 128 characters on all host OS.

Steps

1. Change the privilege setting to advanced:

```
set -privilege advanced
```

2. Configure iSCSI LIFs to return FQDN:

```
vserver iscsi interface modify -vserver SVM_name -lif iscsi_LIF_name
-sendtargets_fqdn FQDN
```

In the following example, the iSCSI LIFs are configured to return storagehost-005.example.com as the FQDN.

```
vserver iscsi interface modify -vserver vs1 -lif vs1_iscsil -sendtargets-fqdn
storagehost-005.example.com
```

3. Verify that sendtargets is the FQDN:

```
vserver iscsi interface show -vserver SVM_name -fields sendtargets-fqdn
```

In this example, storagehost-005.example.com is displayed in the sendtargets-fqdn output field.

```
cluster::vserver*> vserver iscsi interface show -vserver vs1 -fields
sendtargets-fqdn
vserver lif      sendtargets-fqdn
-----
vs1      vs1_iscsil storagehost-005.example.com
vs1      vs1_iscsil2 storagehost-006.example.com
```

[ONTAP 9 Commands](#)

Recommended volume and file or LUN configuration combinations

Recommended volume and file or LUN configuration combinations overview

There are specific combinations of FlexVol volume and file or LUN configurations you can use, depending on your application and administration requirements. Understanding the benefits and costs of these combinations can help you determine the right volume and LUN configuration combination for your environment.

The following volume and LUN configuration combinations are recommended:

- Space-reserved files or LUNs with thick volume provisioning
- Non-space-reserved files or LUNs with thin volume provisioning
- Space-reserved files or LUNs with semi-thick volume provisioning

You can use SCSI thin provisioning on your LUNs in conjunction with any of these configuration combinations.

Space-reserved files or LUNs with thick volume provisioning

Benefits:

- All write operations within space-reserved files are guaranteed; they will not fail due to insufficient space.
- There are no restrictions on storage efficiency and data protection technologies on the volume.

Costs and limitations:

- Enough space must be set aside from the aggregate up front to support the thickly provisioned volume.
- Space equal to twice the size of the LUN is allocated from the volume at LUN creation time.

Non-space-reserved files or LUNs with thin volume provisioning

Benefits:

- There are no restrictions on storage efficiency and data protection technologies on the volume.
- Space is allocated only as it is used.

Costs and restrictions:

- Write operations are not guaranteed; they can fail if the volume runs out of free space.
- You must manage the free space in the aggregate effectively to prevent the aggregate from running out of free space.

Space-reserved files or LUNs with semi-thick volume provisioning

Benefits:

Less space is reserved up front than for thick volume provisioning, and a best-effort write guarantee is still provided.

Costs and restrictions:

- Write operations can fail with this option.

You can mitigate this risk by properly balancing free space in the volume against data volatility.

- You cannot rely on retention of data protection objects such as Snapshot copies and FlexClone files and LUNs.
- You cannot use ONTAP block-sharing storage efficiency capabilities that cannot be automatically deleted, including deduplication, compression, and ODX/Copy Offload.

Determine the correct volume and LUN configuration combination for your environment

Answering a few basic questions about your environment can help you determine the best FlexVol volume and LUN configuration for your environment.

About this task

You can optimize your LUN and volume configurations for maximum storage utilization or for the security of write guarantees. Based on your requirements for storage utilization and your ability to monitor and replenish free space quickly, you must determine the FlexVol volume and LUN volumes appropriate for your installation.

You do not need a separate volume for each LUN.

Step

1. Use the following decision tree to determine the best volume and LUN configuration combination for your environment:

Calculate rate of data growth for LUNs

You need to know the rate at which your LUN data is growing over time to determine whether you should use space-reserved LUNs or non-space-reserved LUNs.

About this task

If you have a consistently high rate of data growth, then space-reserved LUNs might be a better option for you. If you have a low rate of data growth, then you should consider non-space-reserved LUNs.

You can use tools such as OnCommand Insight to calculate your rate of data growth or you can calculate it manually. The following steps are for manual calculation.

Steps

1. Set up a space-reserved LUN.
2. Monitor the data on the LUN for a set period of time, such as one week.

Make sure that your monitoring period is long enough to form a representative sample of regularly occurring increases in data growth. For instance, you might consistently have a large amount of data growth at the end of each month.

3. Each day, record in GB how much your data grows.
4. At the end of your monitoring period, add the totals for each day together, and then divide by the number of days in your monitoring period.

This calculation yields your average rate of growth.

Example

In this example, you need a 200 GB LUN. You decide to monitor the LUN for a week and record the following daily data changes:

- Sunday: 20 GB
- Monday: 18 GB
- Tuesday: 17 GB
- Wednesday: 20 GB
- Thursday: 20 GB
- Friday: 23 GB
- Saturday: 22 GB

In this example, your rate of growth is $(20+18+17+20+20+23+22) / 7 = 20$ GB per day.

Configuration settings for space-reserved files or LUNs with thick-provisioned volumes

This FlexVol volume and file or LUN configuration combination provides the ability to use storage efficiency technologies and does not require you to actively monitor your free space, because sufficient space is allocated up front.

The following settings are required to configure a space-reserved file or LUN in a volume using thick provisioning:

Volume setting	Value
Guarantee	Volume
Fractional reserve	100
Snapshot reserve	Any
Snapshot autodelete	Optional
Autogrow	Optional; if enabled, aggregate free space must be actively monitored.

File or LUN setting	Value
Space reservation	Enabled

Configuration settings for non-space-reserved files or LUNs with thin-provisioned volumes

This FlexVol volume and file or LUN configuration combination requires the smallest amount of storage to be allocated up front, but requires active free space management to prevent errors due to lack of space.

The following settings are required to configure a non-space-reserved files or LUN in a thin-provisioned volume:

Volume setting	Value
Guarantee	None
Fractional reserve	0
Snapshot reserve	Any
Snapshot autodelete	Optional
Autogrow	Optional

File or LUN setting	Value
Space reservation	Disabled

Additional considerations

When the volume or aggregate runs out of space, write operations to the file or LUN can fail.

If you do not want to actively monitor free space for both the volume and the aggregate, you should enable

Autogrow for the volume and set the maximum size for the volume to the size of the aggregate. In this configuration, you must monitor aggregate free space actively, but you do not need to monitor the free space in the volume.

Configuration settings for space-reserved files or LUNs with semi-thick volume provisioning

This FlexVol volume and file or LUN configuration combination requires less storage to be allocated up front than the fully provisioned combination, but places restrictions on the efficiency technologies you can use for the volume. Overwrites are fulfilled on a best-effort basis for this configuration combination.

The following settings are required to configure a space-reserved LUN in a volume using semi-thick provisioning:

Volume setting	Value
Guarantee	Volume
Fractional reserve	0
Snapshot reserve	0
Snapshot autodelete	On, with a commitment level of destroy, a destroy list that includes all objects, the trigger set to volume, and all FlexClone LUNs and FlexClone files enabled for automatic deletion.
Autogrow	Optional; if enabled, aggregate free space must be actively monitored.

File or LUN setting	Value
Space reservation	Enabled

Technology restrictions

You cannot use the following volume storage efficiency technologies for this configuration combination:

- Compression
- Deduplication
- ODX and FlexClone Copy Offload
- FlexClone LUNs and FlexClone files not marked for automatic deletion (active clones)
- FlexClone subfiles
- ODX/Copy Offload

Additional considerations

The following facts must be considered when employing this configuration combination:

- When the volume that supports that LUN runs low on space, protection data (FlexClone LUNs and files, Snapshot copies) is destroyed.
- Write operations can time out and fail when the volume runs out of free space.

Compression is enabled by default for AFF platforms. You must explicitly disable compression for any volume for which you want to use semi-thick provisioning on an AFF platform.

Data protection methods in SAN environments

Data protection methods in SAN environments overview

You can protect your data by making copies of it so that it is available for restoration in the event of accidental deletion, application crashes, data corruption, or disaster. Depending on your data protection and backup needs, ONTAP offers a variety of methods that enable you to protect your data.

SnapMirror Business Continuity (SM-BC)

Beginning with general availability in ONTAP 9.9.1, provides Zero Recovery Time Objective (Zero RTO) or Transparent Application Failover (TAF) to enable automatic failover of business-critical applications in SAN environments. SM-BC requires the installation of ONTAP Mediator 1.2 in a configuration with either two AFF clusters or two All SAN Array (ASA) clusters.

[NetApp Documentation: SnapMirror Business Continuity](#)

Snapshot copy

Enables you to manually or automatically create, schedule, and maintain multiple backups of your LUNs. Snapshot copies use only a minimal amount of additional volume space and do not have a performance cost. If your LUN data is accidentally modified or deleted, that data can easily and quickly be restored from one of the latest Snapshot copies.

FlexClone LUNs (FlexClone license required)

Provides point-in-time, writable copies of another LUN in an active volume or in a Snapshot copy. A clone and its parent can be modified independently without affecting each other.

SnapRestore (license required)

Enables you to perform fast, space-efficient, on-request data recovery from Snapshot copies on an entire volume. You can use SnapRestore to restore a LUN to an earlier preserved state without rebooting the storage system.

Data protection mirror copies (SnapMirror license required)

Provides asynchronous disaster recovery by enabling you to periodically create Snapshot copies of data on your volume; copy those Snapshot copies over a local or wide area network to a partner volume, usually on another cluster; and retain those Snapshot copies. The mirror copy on the partner volume provides quick availability and restoration of data from the time of the last Snapshot copy, if the data on the source volume is corrupted or lost.

SnapVault backups (SnapMirror license required)

Provides storage efficient and long-term retention of backups. SnapVault relationships enable you to back up selected Snapshot copies of volumes to a destination volume and retain the backups.

If you conduct tape backups and archival operations, you can perform them on the data that is already backed up on the SnapVault secondary volume.

SnapDrive for Windows or UNIX (SnapDrive license required)

Configures access to LUNs, manages LUNs, and manages storage system Snapshot copies directly from a Windows or UNIX hosts.

Native tape backup and recovery

Support for most existing tape drives are included in ONTAP, as well as a method for tape vendors to dynamically add support for new devices. ONTAP also supports the Remote Magnetic Tape (RMT) protocol, enabling backup and recovery to any capable system.

Effect of moving or copying a LUN on Snapshot copies

Effect of moving or copying a LUN on Snapshot copies overview

Snapshot copies are created at the volume level. If you copy or move a LUN to a different volume, the Snapshot copy policy of the destination volume is applied to the copied or moved volume. If Snapshot copies are not established for the destination volume, Snapshot copies will not be created of the moved or copied LUN.

Restore a single LUN from a Snapshot copy

You can restore a single LUN from a Snapshot copy without restoring the entire volume that contains the single LUN. You can restore the LUN in place or to a new path in the volume. The operation restores only the single LUN without impacting other files or LUNs in the volume. You can also restore files with streams.

What you'll need

- You must have enough space on your volume to complete the restore operation:
 - If you are restoring a space-reserved LUN where the fractional reserve is 0%, you require one times the size of the restored LUN.
 - If you are restoring a space-reserved LUN where the fractional reserve is 100%, you require two times the size of the restored LUN.
 - If you are restoring a non-space-reserved LUN, you only require the actual space used for the restored LUN.
- A Snapshot copy of the destination LUN must have been created.

If the restore operation fails, the destination LUN might be truncated. In such cases, you can use the Snapshot copy to prevent data loss.

- A Snapshot copy of the source LUN must have been created.

In rare cases, the LUN restore can fail, leaving the source LUN unusable. If this occurs, you can use the Snapshot copy to return the LUN to the state just before the restore attempt.

- The destination LUN and source LUN must have the same OS type.

If your destination LUN has a different OS type from your source LUN, your host can lose data access to the destination LUN after the restore operation.

Steps

1. From the host, stop all host access to the LUN.
2. Unmount the LUN on its host so that the host cannot access the LUN.
3. Unmap the LUN:

```
lun mapping delete -vserver vserver_name -volume volume_name -lun lun_name  
-igroup igrup_name
```

4. Determine the Snapshot copy you want to restore your LUN to:

```
volume snapshot show -vserver vserver_name -volume volume_name
```

5. Create a Snapshot copy of the LUN prior to restoring the LUN:

```
volume snapshot create -vserver vserver_name -volume volume_name -snapshot  
snapshot_name
```

6. Restore the specified LUN in a volume:

```
volume snapshot restore-file -vserver vserver_name -volume volume_name  
-snapshot snapshot_name -path lun_path
```

7. Follow the steps on the screen.

8. If necessary, bring the LUN online:

```
lun modify -vserver vserver_name -path lun_path -state online
```

9. If necessary, remap the LUN:

```
lun mapping create -vserver vserver_name -volume volume_name -lun lun_name  
-igroup igrup_name
```

10. From the host, remount the LUN.

11. From the host, restart access to the LUN.

Restore all LUNs in a volume from a Snapshot copy

You can use `volume snapshot restore` command to restore all the LUNs in a

specified volume from a Snapshot copy.

Steps

1. From the host, stop all host access to the LUNs.

Using SnapRestore without stopping all host access to LUNs in the volume can cause data corruption and system errors.

2. Unmount the LUNs on that host so that the host cannot access the LUNs.

3. Unmap your LUNs:

```
lun mapping delete -vserver vserver_name -volume volume_name -lun lun_name  
-igroup igrp_name
```

4. Determine the Snapshot copy to which you want to restore your volume:

```
volume snapshot show -vserver vserver_name -volume volume_name
```

5. Change your privilege setting to advanced:

```
set -privilege advanced
```

6. Restore your data:

```
volume snapshot restore -vserver vserver_name -volume volume_name -snapshot  
snapshot_name
```

7. Follow the instructions on the screen.

8. Remap your LUNs:

```
lun mapping create -vserver vserver_name -volume volume_name -lun lun_name  
-igroup igrp_name
```

9. Verify that your LUNs are online:

```
lun show -vserver vserver_name -path lun_path -fields state
```

10. If your LUNs are not online, bring them online:

```
lun modify -vserver vserver_name -path lun_path -state online
```

11. Change your privilege setting to admin:

```
set -privilege admin
```

12. From the host, remount your LUNs.

13. From the host, restart access to your LUNs.

Delete one or more existing Snapshot copies from a volume

You can manually delete one or more existing Snapshot copies from the volume. You might want to do this if you need more space on your volume.

Steps

1. Use the volume snapshot show command to verify which Snapshot copies you want to delete.

```
cluster::> volume snapshot show -vserver vs3 -volume vol3

                                         ---Blocks---
Vserver   Volume   Snapshot           Size    Total% Used%
-----  -----  -----
vs3       vol3
          snap1.2013-05-01_0015  100KB   0%    38%
          snap1.2013-05-08_0015  76KB    0%    32%
          snap2.2013-05-09_0010  76KB    0%    32%
          snap2.2013-05-10_0010  76KB    0%    32%
          snap3.2013-05-10_1005  72KB    0%    31%
          snap3.2013-05-10_1105  72KB    0%    31%
          snap3.2013-05-10_1205  72KB    0%    31%
          snap3.2013-05-10_1305  72KB    0%    31%
          snap3.2013-05-10_1405  72KB    0%    31%
          snap3.2013-05-10_1505  72KB    0%    31%

10 entries were displayed.
```

2. Use the volume snapshot delete command to delete Snapshot copies.

If you want to...	Enter this command...
Delete a single Snapshot copy	volume snapshot delete -vserver svm_name -volume vol_name -snapshot snapshot_name
Delete multiple Snapshot copies	volume snapshot delete -vserver svm_name -volume vol_name -snapshot snapshot_name1[,snapshot_name2,...]
Delete all Snapshot copies	volume snapshot delete -vserver svm_name -volume vol_name -snapshot *

The following example deletes all Snapshot copies on the volume vol3.

```
cluster::> volume snapshot delete -vserver vs3 -volume vol3 *

10 entries were acted on.
```

Use FlexClone LUNs to protect your data

Use FlexClone LUNs to protect your data overview

A FlexClone LUN is a point-in-time, writeable copy of another LUN in an active volume or in a Snapshot copy. The clone and its parent can be modified independently without affecting each other.

A FlexClone LUN shares space initially with its parent LUN. By default, the FlexClone LUN inherits the space-reserved attribute of the parent LUN. For example, if the parent LUN is non-space-reserved, the FlexClone LUN is also non-space-reserved by default. However, you can create a non-space-reserved FlexClone LUN from a parent that is a space-reserved LUN.

When you clone a LUN, block sharing occurs in the background and you cannot create a volume Snapshot copy until the block sharing is finished.

You must configure the volume to enable the FlexClone LUN automatic deletion function with the `volume snapshot autodelete modify` command. Otherwise, if you want FlexClone LUNs to be deleted automatically but the volume is not configured for FlexClone auto delete, none of the FlexClone LUNs are deleted.

When you create a FlexClone LUN, the FlexClone LUN automatic deletion function is disabled by default. You must manually enable it on every FlexClone LUN before that FlexClone LUN can be automatically deleted. If you are using semi-thick volume provisioning and you want the “best effort” write guarantee provided by this option, you must make *all* FlexClone LUNs available for automatic deletion.

 When you create a FlexClone LUN from a Snapshot copy, the LUN is automatically split from the Snapshot copy by using a space-efficient background process so that the LUN does not continue to depend on the Snapshot copy or consume any additional space. If this background split has not been completed and this Snapshot copy is automatically deleted, that FlexClone LUN is deleted even if you have disabled the FlexClone auto delete function for that FlexClone LUN. After the background split is complete, the FlexClone LUN is not deleted even if that Snapshot copy is deleted.

[Logical storage management](#)

Reasons for using FlexClone LUNs

You can use FlexClone LUNs to create multiple read/write copies of a LUN.

You might want to do this for the following reasons:

- You need to create a temporary copy of a LUN for testing purposes.
- You need to make a copy of your data available to additional users without giving them access to the production data.
- You want to create a clone of a database for manipulation and projection operations, while preserving the original data in an unaltered form.
- You want to access a specific subset of a LUN’s data (a specific logical volume or file system in a volume group, or a specific file or set of files in a file system) and copy it to the original LUN, without restoring the rest of the data in the original LUN. This works on operating systems that support mounting a LUN and a clone of the LUN at the same time. SnapDrive for UNIX supports this with the `snap connect` command.

- You need multiple SAN boot hosts with the same operating system.

How a FlexVol volume can reclaim free space with autodelete setting

You can enable the autodelete setting of a FlexVol volume to automatically delete FlexClone files and FlexClone LUNs. By enabling autodelete, you can reclaim a target amount of free space in the volume when a volume is nearly full.

You can configure a volume to automatically start deleting FlexClone files and FlexClone LUNs when the free space in the volume decreases below a particular threshold value, and automatically stop deleting clones when a target amount of free space in the volume is reclaimed. Although, you cannot specify the threshold value that starts the automatic deletion of clones, you can specify whether a clone is eligible for deletion, and you can specify the target amount of free space for a volume.

A volume automatically deletes FlexClone files and FlexClone LUNs when the free space in the volume decreases below a particular threshold and when *both* of the following requirements are met:

- The autodelete capability is enabled for the volume that contains the FlexClone files and FlexClone LUNs.

You can enable the autodelete capability for a FlexVol volume by using the `volume snapshot autodelete modify` command. You must set the `-trigger` parameter to `volume` or `snap_reserve` for a volume to automatically delete FlexClone files and FlexClone LUNs.

- The autodelete capability is enabled for the FlexClone files and FlexClone LUNs.

You can enable autodelete for a FlexClone file or FlexClone LUN by using the `file clone create` command with the `-autodelete` parameter. As a result, you can preserve certain FlexClone files and FlexClone LUNs by disabling autodelete for the clones and ensuring that other volume settings do not override the clone setting.

Configure a FlexVol volume to automatically delete FlexClone files and FlexClone LUNs

You can enable a FlexVol volume to automatically delete FlexClone files and FlexClone LUNs with autodelete enabled when the free space in the volume decreases below a particular threshold.

What you'll need

- The FlexVol volume must contain FlexClone files and FlexClone LUNs and be online.
- The FlexVol volume must not be a read-only volume.

Steps

1. Enable automatic deletion of FlexClone files and FlexClone LUNs in the FlexVol volume by using the `volume snapshot autodelete modify` command.
 - For the `-trigger` parameter, you can specify `volume` or `snap_reserve`.
 - For the `-destroy-list` parameter, you must always specify `lun_clone`, `file_clone` regardless of whether you want to delete only one type of clone.

The following example shows how you can enable volume `vol1` to trigger the automatic deletion of FlexClone files and FlexClone LUNs for space reclamation until 25% of the volume consists of free space:

```
cluster1::> volume snapshot autodelete modify -vserver vs1 -volume vol1 -enabled true -commitment disrupt -trigger volume -target-free-space 25 -destroy-list lun_clone,file_clone
```

```
Volume modify successful on volume:vol1
```

While enabling FlexVol volumes for automatic deletion, if you set the value of the `-commitment` parameter to `destroy`, all the FlexClone files and FlexClone LUNs with the `-autodelete` parameter set to `true` might be deleted when the free space in the volume decreases below the specified threshold value. However, FlexClone files and FlexClone LUNs with the `-autodelete` parameter set to `false` will not be deleted.

2. Verify that automatic deletion of FlexClone files and FlexClone LUNs is enabled in the FlexVol volume by using the `volume snapshot autodelete show` command.

The following example shows that volume `vol1` is enabled for automatic deletion of FlexClone files and FlexClone LUNs:

```
cluster1::> volume snapshot autodelete show -vserver vs1 -volume vol1

Vserver Name: vs1
Volume Name: vol1
Enabled: true
Commitment: disrupt
Defer Delete: user_created
Delete Order: oldest_first
Defer Delete Prefix: (not specified)*
Target Free Space: 25%
Trigger: volume
Destroy List: lun_clone,file_clone
Is Constituent Volume: false
```

3. Ensure that `autodelete` is enabled for the FlexClone files and FlexClone LUNs in the volume that you want to delete by performing the following steps:

- a. Enable automatic deletion of a particular FlexClone file or FlexClone LUN by using the `volume file clone autodelete` command.

You can force a specific FlexClone file or FlexClone LUN to be automatically deleted by using the `volume file clone autodelete` command with the `-force` parameter.

The following example shows that automatic deletion of the FlexClone LUN `lun1_clone` contained in volume `vol1` is enabled:

```
cluster1::> volume file clone autodelete -vserver vs1 -clone-path  
/vol/vol1/lun1_clone -enabled true
```

You can enable autodelete when you create FlexClone files and FlexClone LUNs.

- b. Verify that the FlexClone file or FlexClone LUN is enabled for automatic deletion by using the `volume file clone show-autodelete` command.

The following example shows that the FlexClone LUN `lun1_clone` is enabled for automatic deletion:

```
cluster1::> volume file clone show-autodelete -vserver vs1 -clone  
-path vol/vol1/lun1_clone  
Vserver  
Name: vs1  
Clone  
Path: vol/vol1/lun1_clone  
  
**Autodelete Enabled: true**
```

For more information about using the commands, see the respective man pages.

Clone LUNs from an active volume

You can create copies of your LUNs by cloning the LUNs in the active volume. These FlexClone LUNs are readable and writeable copies of the original LUNs in the active volume.

What you'll need

A FlexClone license must be installed.

About this task

A space-reserved FlexClone LUN requires as much space as the space-reserved parent LUN. If the FlexClone LUN is not space-reserved, you must ensure that the volume has enough space to accommodate changes to the FlexClone LUN.

Steps

1. You must have verified that the LUNs are not mapped to an igroup or are written to before making the clone.
2. Use the `lun show` command to verify that the LUN exists.

```
lun show -vserver vs1
```

Vserver	Path	State	Mapped	Type	Size
vs1	/vol/vol1/lun1	online	unmapped	windows	47.07MB

3. Use the volume file clone create command to create the FlexClone LUN.

```
volume file clone create -vserver vs1 -volume vol1 -source-path lun1  
-destination-path/lun1_clone
```

If you need the FlexClone LUN to be available for automatic deletion, you include `-autodelete true`. If you are creating this FlexClone LUN in a volume using semi-thick provisioning, you must enable automatic deletion for all FlexClone LUNs.

4. Use the lun show command to verify that you created a LUN.

```
lun show -vserver vs1
```

Vserver	Path	State	Mapped	Type	Size
vs1	/vol/volX/lun1	online	unmapped	windows	47.07MB
vs1	/vol/volX/lun1_clone	online	unmapped	windows	47.07MB

Create FlexClone LUNs from a Snapshot copy in a volume

You can use a Snapshot copy in your volume to create FlexClone copies of your LUNs. FlexClone copies of LUNs are both readable and writeable.

What you'll need

A FlexClone license must be installed.

About this task

The FlexClone LUN inherits the space reservations attribute of the parent LUN. A space-reserved FlexClone LUN requires as much space as the space-reserved parent LUN. If the FlexClone LUN is not space-reserved, the volume must have enough space to accommodate changes to the clone.

Steps

1. Verify that the LUN is not mapped or being written to.
2. Create a Snapshot copy of the volume that contains the LUNs:

```
volume snapshot create -vserver vserver_name -volume volume_name -snapshot  
snapshot_name
```

You must create a Snapshot copy (the backing Snapshot copy) of the LUN you want to clone.

3. Create the FlexClone LUN from the Snapshot copy:

```
file clone create -vserver vserver_name -volume volume_name -source-path  
source_path -snapshot-name snapshot_name -destination-path destination_path
```

If you need the FlexClone LUN to be available for automatic deletion, you include `-autodelete true`. If you are creating this FlexClone LUN in a volume using semi-thick provisioning, you must enable automatic deletion for all FlexClone LUNs.

4. Verify that the FlexClone LUN is correct:

```
lun show -vserver vserver_name
```

Vserver	Path	State	Mapped	Type	Size
vs1	/vol/vol1/lun1_clone	online	unmapped	windows	47.07MB
vs1	/vol/vol1/lun1_snap_clone	online	unmapped	windows	47.07MB

Prevent a specific FlexClone file or FlexClone LUN from being automatically deleted

If you configure a FlexVol volume to automatically delete FlexClone files and FlexClone LUNs, any clone that fits the criteria you specify might be deleted. If you have specific FlexClone files or FlexClone LUNs that you want to preserve, you can exclude them from the automatic FlexClone deletion process.

What you'll need

A FlexClone license must be installed.

About this task

When you create a FlexClone file or FlexClone LUN, by default the autodelete setting for the clone is disabled. FlexClone files and FlexClone LUNs with autodelete disabled are preserved when you configure a FlexVol volume to automatically delete clones to reclaim space on the volume.

If you set the commitment level on the volume to try or disrupt, you can individually preserve specific FlexClone files or FlexClone LUNs by disabling autodelete for those clones.

However, if you set the commitment level on the volume to destroy and the destroy lists include lun_clone, file_clone, the volume setting overrides the clone setting, and all FlexClone files and FlexClone LUNs can be deleted regardless of the autodelete setting for the clones.

Steps

1. Prevent a specific FlexClone file or FlexClone LUN from being automatically deleted by using the `volume file clone autodelete` command.

The following example shows how you can disable autodelete for FlexClone LUN lun1_clone contained in vol1:

```
cluster1::> volume file clone autodelete -vserver vs1 -volume vol1  
-clone-path lun1_clone -enable false
```

A FlexClone file or FlexClone LUN with autodelete disabled cannot be deleted automatically to reclaim space on the volume.

2. Verify that autodelete is disabled for the FlexClone file or FlexClone LUN by using the `volume file clone show-autodelete` command.

The following example shows that autodelete is false for the FlexClone LUN lun1_clone:

```
cluster1::> volume file clone show-autodelete -vserver vs1 -clone-path  
vol/vol1/lun1_clone  
Name: vs1  
Clone Path:  
vol/vol1/lun1_clone  
Enabled: false  
Autodelete
```

Configure and use SnapVault backups in a SAN environment

Configure and use SnapVault backups in a SAN environment overview

SnapVault configuration and use in a SAN environment is very similar to configuration and use in a NAS environment, but restoring LUNs in a SAN environment requires some special procedures.

SnapVault backups contain a set of read-only copies of a source volume. In a SAN environment you always back up entire volumes to the SnapVault secondary volume, not individual LUNs.

The procedure for creating and initializing the SnapVault relationship between a primary volume containing LUNs and a secondary volume acting as a SnapVault backup is identical to the procedure used with FlexVol volumes used for file protocols. This procedure is described in detail in [Data Protection](#).

It is important to ensure that LUNs being backed up are in a consistent state before the Snapshot copies are created and copied to the SnapVault secondary volume. Automating the Snapshot copy creation with SnapCenter ensures that backed up LUNs are complete and usable by the original application.

There are three basic choices for restoring LUNs from a SnapVault secondary volume:

- You can map a LUN directly from the SnapVault secondary volume and connect a host to the LUN to access the contents of the LUN.

The LUN is read-only and you can map only from the most recent Snapshot copy in the SnapVault backup. Persistent reservations and other LUN metadata are lost. If desired, you can use a copy program on the host to copy the LUN contents back to the original LUN if it is still accessible.

The LUN has a different serial number from the source LUN.

- You can clone any Snapshot copy in the SnapVault secondary volume to a new read-write volume.

You can then map any of the LUNs in the volume and connect a host to the LUN to access the contents of the LUN. If desired, you can use a copy program on the host to copy the LUN contents back to the original LUN if it is still accessible.

- You can restore the entire volume containing the LUN from any Snapshot copy in the SnapVault secondary volume.

Restoring the entire volume replaces all of the LUNs, and any files, in the volume. Any new LUNs created

since the Snapshot copy was created are lost.

The LUNs retain their mapping, serial numbers, UUIDs, and persistent reservations.

Access a read-only LUN copy from a SnapVault backup

You can access a read-only copy of a LUN from the latest Snapshot copy in a SnapVault backup. The LUN ID, path, and serial number are different from the source LUN and must first be mapped. Persistent reservations, LUN mappings, and igroups are not replicated to the SnapVault secondary volume.

What you'll need

- The SnapVault relationship must be initialized and the latest Snapshot copy in the SnapVault secondary volume must contain the desired LUN.
- The storage virtual machine (SVM) containing the SnapVault backup must have one or more LIFs with the desired SAN protocol accessible from the host used to access the LUN copy.
- If you plan to access LUN copies directly from the SnapVault secondary volume, you must create your igroups on the SnapVault SVM in advance.

You can access a LUN directly from the SnapVault secondary volume without having to first restore or clone the volume containing the LUN.

About this task

If a new Snapshot copy is added to the SnapVault secondary volume while you have a LUN mapped from a previous Snapshot copy, the contents of the mapped LUN changes. The LUN is still mapped with the same identifiers, but the data is taken from the new Snapshot copy. If the LUN size changes, some hosts automatically detect the size change; Windows hosts require a disk rescan to pick up any size change.

Steps

1. Run the `lun show` command to list the available LUNs in the SnapVault secondary volume.

In this example, you can see both the original LUNs in the primary volume `srcvolA` and the copies in the SnapVault secondary volume `dstvolB`:

cluster::> lun show						
Vserver	Path	State	Mapped	Type	Size	
vserverA	/vol/srcvolA/lun_A	online	mapped	windows	300.0GB	
vserverA	/vol/srcvolA/lun_B	online	mapped	windows	300.0GB	
vserverA	/vol/srcvolA/lun_C	online	mapped	windows	300.0GB	
vserverB	/vol/dstvolB/lun_A	online	unmapped	windows	300.0GB	
vserverB	/vol/dstvolB/lun_B	online	unmapped	windows	300.0GB	
vserverB	/vol/dstvolB/lun_C	online	unmapped	windows	300.0GB	

6 entries were displayed.

2. If the igroup for the desired host does not already exist on the SVM containing the SnapVault secondary volume, run the `igroup create` command to create an igroup.

This command creates an igroup for a Windows host that uses the iSCSI protocol:

```
cluster::> igrup create -vserver vserverB -igroup temp_igroup  
-protocol iscsi -ostype windows  
-initiator iqn.1991-05.com.microsoft:hostA
```

3. Run the `lun mapping create` command to map the desired LUN copy to the igroup.

```
cluster::> lun mapping create -vserver vserverB -path /vol/dstvolB/lun_A  
-igroup temp_igroup
```

4. Connect the host to the LUN and access the contents of the LUN as desired.

Restore a single LUN from a SnapVault backup

You can restore a single LUN to a new location or to the original location. You can restore from any Snapshot copy in the SnapVault secondary volume. To restore the LUN to the original location, you first restore it to a new location and then copy it.

What you'll need

- The SnapVault relationship must be initialized and the SnapVault secondary volume must contain an appropriate Snapshot copy to restore.
- The storage virtual machine (SVM) containing the SnapVault secondary volume must have one or more LIFs with the desired SAN protocol that are accessible from the host used to access the LUN copy.
- The igroups must already exist on the SnapVault SVM.

About this task

The process includes creating a read-write volume clone from a Snapshot copy in the SnapVault secondary volume. You can use the LUN directly from the clone, or you can optionally copy the LUN contents back to the original LUN location.

The LUN in the clone has a different path and serial number from the original LUN. Persistent reservations are not retained.

Steps

1. Run the `snapmirror show` command to verify the secondary volume that contains the SnapVault backup.

```

cluster::> snapmirror show

Source          Dest      Mirror   Relation   Total           Last
Path           Type     Path      State    Status   Progress  Healthy Updated
-----  -----  -----  -----  -----  -----  -----  -----
vserverA:srcvolA
                XDP  vserverB:dstvolB
                                Snapmirrored
                                Idle        -         true       -

```

- Run the `volume snapshot show` command to identify the Snapshot copy that you want to restore the LUN from.

```

cluster::> volume snapshot show

Vserver  Volume  Snapshot          State  Size  Total% Used%
-----  -----  -----  -----  -----  -----  -----  -----
vserverB
        dstvolB
            snap2.2013-02-10_0010  valid  124KB    0%    0%
            snap1.2013-02-10_0015  valid  112KB    0%    0%
            snap2.2013-02-11_0010  valid  164KB    0%    0%

```

- Run the `volume clone create` command to create a read-write clone from the desired Snapshot copy.

The volume clone is created in the same aggregate as the SnapVault backup. There must be enough space in the aggregate to store the clone.

```

cluster::> volume clone create -vserver vserverB
        -flexclone dstvolB_clone -type RW -parent-volume dstvolB
        -parent-snapshot daily.2013-02-10_0010
[Job 108] Job succeeded: Successful

```

- Run the `lun show` command to list the LUNs in the volume clone.

```

cluster::> lun show -vserver vserverB -volume dstvolB_clone

Vserver      Path          State   Mapped   Type
-----  -----
vserverB    /vol/dstvolB_clone/lun_A  online  unmapped windows
vserverB    /vol/dstvolB_clone/lun_B  online  unmapped windows
vserverB    /vol/dstvolB_clone/lun_C  online  unmapped windows

3 entries were displayed.

```

5. If the igroup for the desired host does not already exist on the SVM containing the SnapVault backup, run the `igroup create` command to create an igroup.

This example creates an igroup for a Windows host that uses the iSCSI protocol:

```

cluster::> igrup create -vserver vserverB -igroup temp_igroup
             -protocol iscsi -ostype windows
             -initiator iqn.1991-05.com.microsoft:hostA

```

6. Run the `lun mapping create` command to map the desired LUN copy to the igroup.

```

cluster::> lun mapping create -vserver vserverB
             -path /vol/dstvolB_clone/lun_C -igroup temp_igroup

```

7. Connect the host to the LUN and access the contents of the LUN, as desired.

The LUN is read-write and can be used in place of the original LUN. Because the LUN serial number is different, the host interprets it as a different LUN from the original.

8. Use a copy program on the host to copy the LUN contents back to the original LUN.

Restore all LUNs in a volume from a SnapVault backup

If one or more LUNs in a volume need to be restored from a SnapVault backup, you can restore the entire volume. Restoring the volume affects all LUNs in the volume.

What you'll need

The SnapVault relationship must be initialized and the SnapVault secondary volume must contain an appropriate Snapshot copy to restore.

About this task

Restoring an entire volume returns the volume to the state it was in when the Snapshot copy was made. If a LUN was added to the volume after the Snapshot copy, that LUN is removed during the restore process.

After restoring the volume, the LUNs remain mapped to the igroups they were mapped to just before the restore. The LUN mapping might be different from the mapping at the time of the Snapshot copy. Persistent

reservations on the LUNs from host clusters are retained.

Steps

1. Stop I/O to all LUNs in the volume.
2. Run the `snapmirror show` command to verify the secondary volume that contains the SnapVault secondary volume.

```
cluster::> snapmirror show

Source          Dest      Mirror  Relation   Total           Last
Path           Type     Path     State    Status   Progress  Healthy Updated
-----  -----  -----  -----  -----  -----  -----  -----
vserverA:srcvolA
              XDP  vserverB:dstvolB
                           Snapmirrored
                           Idle       -        true      -

```

3. Run the `volume snapshot show` command to identify the Snapshot copy that you want to restore from.

```
cluster::> volume snapshot show

Vserver  Volume  Snapshot          State  Size  Total% Used%
-----  -----  -----  -----
vserverB
      dstvolB
          snap2.2013-02-10_0010  valid  124KB    0%    0%
          snap1.2013-02-10_0015  valid  112KB    0%    0%
          snap2.2013-02-11_0010  valid  164KB    0%    0%
```

4. Run the `snapmirror restore` command and specify the `-source-snapshot` option to specify the Snapshot copy to use.

The destination you specify for the restore is the original volume you are restoring to.

```
cluster::> snapmirror restore -destination-path vserverA:srcvolA
               -source-path vserverB:dstvolB -source-snapshot daily.2013-02-10_0010

Warning: All data newer than Snapshot copy hourly.2013-02-11_1205 on
volume vserverA:src_volA will be deleted.
Do you want to continue? {y|n}: y
[Job 98] Job is queued: snapmirror restore from source
"vserverB:dstvolB" for the snapshot daily.2013-02-10_0010.
```

5. If you are sharing LUNs across a host cluster, restore the persistent reservations on the LUNs from the

affected hosts.

Restoring a volume from a SnapVault backup

In the following example, the LUN named lun_D was added to the volume after the Snapshot copy was created. After restoring the entire volume from the Snapshot copy, lun_D no longer appears.

In the lun show command output, you can see the LUNs in the primary volume srcvolA and the read-only copies of those LUNs in the SnapVault secondary volume dstvolB. There is no copy of lun_D in the SnapVault backup.

```
cluster::> lun show
Vserver    Path          State   Mapped   Type      Size
-----  -----
vserverA  /vol/srcvolA/lun_A  online  mapped   windows  300.0GB
vserverA  /vol/srcvolA/lun_B  online  mapped   windows  300.0GB
vserverA  /vol/srcvolA/lun_C  online  mapped   windows  300.0GB
vserverA  /vol/srcvolA/lun_D  online  mapped   windows  250.0GB
vserverB  /vol/dstvolB/lun_A  online  unmapped windows  300.0GB
vserverB  /vol/dstvolB/lun_B  online  unmapped windows  300.0GB
vserverB  /vol/dstvolB/lun_C  online  unmapped windows  300.0GB
```

7 entries were displayed.

```
cluster::>snapmirror restore -destination-path vserverA:srcvolA
           -source-path vserverB:dstvolB
           -source-snapshot daily.2013-02-10_0010
```

Warning: All data newer than Snapshot copy hourly.2013-02-11_1205
on volume vserverA:src.volA will be deleted.

Do you want to continue? {y|n}: y

[Job 98] Job is queued: snapmirror restore from source
"vserverB:dstvolB" for the snapshot daily.2013-02-10_0010.

```
cluster::> lun show
Vserver    Path          State   Mapped   Type      Size
-----  -----
vserverA  /vol/srcvolA/lun_A  online  mapped   windows  300.0GB
vserverA  /vol/srcvolA/lun_B  online  mapped   windows  300.0GB
vserverA  /vol/srcvolA/lun_C  online  mapped   windows  300.0GB
vserverB  /vol/dstvolB/lun_A  online  unmapped windows  300.0GB
vserverB  /vol/dstvolB/lun_B  online  unmapped windows  300.0GB
vserverB  /vol/dstvolB/lun_C  online  unmapped windows  300.0GB
```

6 entries were displayed.

After the volume is restored from the SnapVault secondary volume, the source volume no longer contains

Iun_D. You do not need to remap the LUNs in the source volume after the restore because they are still mapped.

How you can connect a host backup system to the primary storage system

You can back up SAN systems to tape through a separate backup host to avoid performance degradation on the application host.

It is imperative that you keep SAN and NAS data separated for backup purposes. The figure below shows the recommended physical configuration for a host backup system to the primary storage system. You must configure volumes as SAN-only. LUNs can be confined to a single volume or the LUNs can be spread across multiple volumes or storage systems.

Volumes on a host can consist of a single LUN mapped from the storage system or multiple LUNs using a volume manager, such as VxVM on HP-UX systems.

Back up a LUN through a host backup system

You can use a cloned LUN from a Snapshot copy as source data for the host backup system.

What you'll need

A production LUN must exist and be mapped to an igroup that includes the WWPN or initiator node name of the application server. The LUN must also be formatted and accessible to the host

Steps

1. Save the contents of the host file system buffers to disk.

You can use the command provided by your host operating system, or you can use SnapDrive for Windows or SnapDrive for UNIX. You can also opt to make this step part of your SAN backup pre-processing script.

2. Use the `volume snapshot create` command to create a Snapshot copy of the production LUN.

```
volume snapshot create -vserver vs0 -volume vol3 -snapshot vol3_snapshot  
-comment "Single snapshot" -foreground false
```

3. Use the `volume file clone create` command to create a clone of the production LUN.

```
volume file clone create -vserver vs3 -volume vol3 -source-path lun1 -snapshot  
-name snap_vol3 -destination-path lun1_backup
```

4. Use the `lun igrup create` command to create an igrup that includes the WWPN of the backup server.

```
lun igrup create -vserver vs3 -igroup igrup3 -protocol fc -ostype windows  
-initiator 10:00:00:00:c9:73:5b:91
```

5. Use the `lun mapping create` command to map the LUN clone you created in Step 3 to the backup host.

```
lun mapping create -vserver vs3 -volume vol3 -lun lun1_backup -igroup igrup3
```

You can opt to make this step part of your SAN backup application's post-processing script.

6. From the host, discover the new LUN and make the file system available to the host.

You can opt to make this step part of your SAN backup application's post-processing script.

7. Back up the data in the LUN clone from the backup host to tape by using your SAN backup application.

8. Use the `lun modify` command to take the LUN clone offline.

```
lun modify -vserver vs3 -path /vol/vol3/lun1_backup -state offline
```

9. Use the `lun delete` to remove the LUN clone.

```
lun delete -vserver vs3 -volume vol3 -lun lun1_backup
```

10. Use the `volume snapshot delete` command to remove the Snapshot copy.

```
volume snapshot delete -vserver vs3 -volume vol3 -snapshot vol3_snapshot
```

SAN configurations in a MetroCluster environment

SAN configurations in a MetroCluster environment

You must be aware of certain considerations when using SAN configurations in a MetroCluster environment.

- MetroCluster configurations do not support front-end FC fabric “routed” vSAN configurations.
- Beginning with ONTAP 9.12.1, four-node MetroCluster IP configurations are supported on NVMe/FC. MetroCluster configurations are not supported for NVMe prior to ONTAP 9.12.1.
- Other SAN protocols such as iSCSI, FC, and FCoE are supported on MetroCluster configurations.
- When using SAN client configurations, you must check whether any special considerations for MetroCluster configurations are included in the notes that are provided in the [NetApp Interoperability Matrix Tool \(IMT\)](#).
- Operating systems and applications must provide an I/O resiliency of 120 seconds to support MetroCluster automatic unplanned switchover and Tiebreaker or Mediator-initiated switchover.
- The MetroCluster is using the same WWPNs on both sides of the front-end SAN.

Related information

[Understanding MetroCluster data protection and disaster recovery](#)

For further MetroCluster-specific host information, refer to the following NetApp Knowledge Base articles:

[What are AIX Host support considerations in a MetroCluster configuration?](#)

[Solaris host support considerations in a MetroCluster configuration](#)

Prevent port overlap between switchover and switchback

In a SAN environment, you can configure the front-end switches to avoid overlap when the old port goes offline and the new port comes online.

During switchover, the FC port on the surviving site might log in to the fabric before the fabric has detected that the FC port on the disaster site is offline and has removed this port from the name and directory services.

If the FC port on the disaster is not yet removed, the fabric login attempt of the FC port at the surviving site might be rejected due to a duplicate WWPN. This behavior of the FC switches can be changed to honor the login of the previous device and not the existing one. You should verify the effects of this behavior on other fabric devices. Contact the switch vendor for more information.

Choose the correct procedure according to your switch type.

Example 10. Steps

Cisco switch

1. Connect to the switch and log in.
2. Enter configuration mode:

```
switch# config t  
switch(config) #
```

3. Overwrite the first device entry in the name server database with the new device:

```
switch(config) # no fcns reject-duplicate-pwwn vsan 1
```

4. In switches that are running NX-OS 8.x, confirm that the flogi quiesce timeout is set to zero:

- a. Display the quiesce timerval:

```
switch(config) # show flogi interval info \| i quiesce
```

```
Stats: fs flogi quiesce timerval: 0
```

- b. If the output in the previous step does not indicate that the timerval is zero, then set it to zero:

```
switch(config) # flogi scale enable
```

```
switch(config) $ flogi quiesce timeout 0
```

Brocade switch

1. Connect to the switch and log in.
2. Enter the switchDisable command.
3. Enter the configure command, and press **y** at the prompt.

```
F-Port login parameters (yes, y, no, n): [no] y
```

4. Choose setting 1:

```
- 0: First login take precedence over the second login (default)  
- 1: Second login overrides first login.  
- 2: the port type determines the behavior  
Enforce FLOGI/FDISC login: (0..2) [0] 1
```

5. Respond to the remaining prompts, or press **Ctrl + D**.

6. Enter the `switchEnable` command.

SAN concepts

About SAN host provisioning

SAN provisioning with iSCSI

In SAN environments, storage systems are targets that have storage target devices. For iSCSI and FC, the storage target devices are referred to as LUNs (logical units). For Non-Volatile Memory Express (NVMe) over Fibre Channel, the storage target devices are referred to as namespaces.

You configure storage by creating LUNs for iSCSI and FC or by creating namespaces for NVMe. The LUNs or namespaces are then accessed by hosts using Internet Small Computer Systems Interface (iSCSI) or Fibre Channel (FC) protocol networks.

To connect to iSCSI networks, hosts can use standard Ethernet network adapters (NICs), TCP offload engine (TOE) cards with software initiators, converged network adapters (CNAs), or dedicated iSCSI host bus adapters (HBAs).

To connect to FC networks, hosts require FC HBAs or CNAs.

Supported FC protocols include:

- FC
- FCoE
- NVMe

iSCSI target node network connections and names

iSCSI target nodes can connect to the network in several ways:

- Over Ethernet interfaces using software that is integrated into ONTAP.
- Over multiple system interfaces, with an interface used for iSCSI that can also transmit traffic for other protocols, such as SMB and NFS.
- Using a unified target adapter (UTA) or a converged network adapter (CNA).

Every iSCSI node must have a node name.

The two formats, or type designators, for iSCSI node names are *iqn* and *eui*. The SVM iSCSI target always uses the *iqn*-type designator. The initiator can use either the *iqn*-type or *eui*-type designator.

Storage system node name

Each SVM running iSCSI has a default node name based on a reverse domain name and a unique encoding number.

The node name is displayed in the following format:

`iqn.1992-08.com.netapp:sn.unique-encoding-number`

The following example shows the default node name for a storage system with a unique encoding number:

`iqn.1992-08.com.netapp:sn.812921059e6c11e097b3123478563412:vs.6`

TCP port for iSCSI

The iSCSI protocol is configured in ONTAP to use TCP port number 3260.

ONTAP does not support changing the port number for iSCSI. Port number 3260 is registered as part of the iSCSI specification and cannot be used by any other application or service.

Related information

[NetApp Documentation: ONTAP SAN Host Configuration](#)

iSCSI service management

iSCSI service management

You can manage the availability of the iSCSI service on the iSCSI logical interfaces of the storage virtual machine (SVM) by using the `vserver iscsi interface enable` or `vserver iscsi interface disable` commands.

By default, the iSCSI service is enabled on all iSCSI logical interfaces.

How iSCSI is implemented on the host

iSCSI can be implemented on the host using hardware or software.

You can implement iSCSI in one of the following ways:

- Using Initiator software that uses the host's standard Ethernet interfaces.
- Through an iSCSI host bus adapter (HBA): An iSCSI HBA appears to the host operating system as a SCSI disk adapter with local disks.
- Using a TCP Offload Engine (TOE) adapter that offloads TCP/IP processing.

The iSCSI protocol processing is still performed by host software.

How iSCSI authentication works

During the initial stage of an iSCSI session, the initiator sends a login request to the storage system to begin an iSCSI session. The storage system then either permits or denies the login request, or determine that a login is not required.

iSCSI authentication methods are:

- Challenge Handshake Authentication Protocol (CHAP)--The initiator logs in using a CHAP user name and password.

You can specify a CHAP password or generate a hexadecimal secret password. There are two types of CHAP user names and passwords:

- Inbound—The storage system authenticates the initiator.

Inbound settings are required if you are using CHAP authentication.

- Outbound—This is an optional setting to enable the initiator to authenticate the storage system.

You can use outbound settings only if you define an inbound user name and password on the storage system.

- deny—The initiator is denied access to the storage system.
- none—The storage system does not require authentication for the initiator.

You can define the list of initiators and their authentication methods. You can also define a default authentication method that applies to initiators that are not on this list.

Related information

[Windows Multipathing Options with Data ONTAP: Fibre Channel and iSCSI](#)

iSCSI initiator security management

ONTAP provides a number of features for managing security for iSCSI initiators. You can define a list of iSCSI initiators and the authentication method for each, display the initiators and their associated authentication methods in the authentication list, add and remove initiators from the authentication list, and define the default iSCSI initiator authentication method for initiators not in the list.

iSCSI endpoint isolation

Beginning with ONTAP 9.1 existing iSCSI security commands were enhanced to accept an IP address range, or multiple IP addresses.

All iSCSI initiators must provide origination IP addresses when establishing a session or connection with a target. This new functionality prevents an initiator from logging into the cluster if the origination IP address is unsupported or unknown, providing a unique identification scheme. Any initiator originating from an unsupported or unknown IP address will have their login rejected at the iSCSI session layer, preventing the initiator from accessing any LUN or volume within the cluster.

Implement this new functionality with two new commands to help manage pre-existing entries.

Add initiator address range

Improve iSCSI initiator security management by adding an IP address range, or multiple IP addresses with the vserver iscsi security add-initiator-address-range command.

```
cluster1::> vserver iscsi security add-initiator-address-range
```

Remove initiator address range

Remove an IP address range, or multiple IP addresses, with the vserver iscsi security remove-

initiator-address-range command.

```
cluster1::> vserver iscsi security remove-initiator-address-range
```

What CHAP authentication is

The Challenge Handshake Authentication Protocol (CHAP) enables authenticated communication between iSCSI initiators and targets. When you use CHAP authentication, you define CHAP user names and passwords on both the initiator and the storage system.

During the initial stage of an iSCSI session, the initiator sends a login request to the storage system to begin the session. The login request includes the initiator's CHAP user name and CHAP algorithm. The storage system responds with a CHAP challenge. The initiator provides a CHAP response. The storage system verifies the response and authenticates the initiator. The CHAP password is used to compute the response.

Guidelines for using CHAP authentication

You should follow certain guidelines when using CHAP authentication.

- If you define an inbound user name and password on the storage system, you must use the same user name and password for outbound CHAP settings on the initiator. If you also define an outbound user name and password on the storage system to enable bidirectional authentication, you must use the same user name and password for inbound CHAP settings on the initiator.
- You cannot use the same user name and password for inbound and outbound settings on the storage system.
- CHAP user names can be 1 to 128 bytes.

A null user name is not allowed.

- CHAP passwords (secrets) can be 1 to 512 bytes.

Passwords can be hexadecimal values or strings. For hexadecimal values, you should enter the value with a prefix of "0x" or "0X". A null password is not allowed.

ONTAP allows the use of special characters, non-English letters, numbers and spaces for CHAP passwords (secrets). However, this is subject to host restrictions. If any of these are not allowed by your specific host, they cannot be used.

For example, the Microsoft iSCSI software initiator requires both the initiator and target CHAP passwords to be at least 12 bytes if IPsec encryption is not being used. The maximum password length is 16 bytes regardless of whether IPsec is used.

For additional restrictions, you should see the initiator's documentation.

How using iSCSI interface access lists to limit initiator interfaces can increase performance and security

iSCSI interface access lists can be used to limit the number of LIFs in an SVM that an initiator can access, thereby increasing performance and security.

When an initiator begins a discovery session using an iSCSI `SendTargets` command, it receives the IP addresses associated with the LIF (network interface) that is in the access list. By default, all initiators have access to all iSCSI LIFs in the SVM. You can use the access list to restrict the number of LIFs in an SVM that an initiator has access to.

iSNS server registration requirement

What iSNS is

The Internet Storage Name Service (iSNS) is a protocol that enables automated discovery and management of iSCSI devices on a TCP/IP storage network. An iSNS server maintains information about active iSCSI devices on the network, including their IP addresses, iSCSI node names IQN's, and portal groups.

You can obtain an iSNS server from a third-party vendor. If you have an iSNS server on your network configured and enabled for use by the initiator and target, you can use the management LIF for a storage virtual machine (SVM) to register all the iSCSI LIFs for that SVM on the iSNS server. After the registration is complete, the iSCSI initiator can query the iSNS server to discover all the LIFs for that particular SVM.

If you decide to use an iSNS service, you must ensure that your storage virtual machines (SVMs) are properly registered with an Internet Storage Name Service (iSNS) server.

If you do not have an iSNS server on your network, you must manually configure each target to be visible to the host.

What an iSNS server does

An iSNS server uses the Internet Storage Name Service (iSNS) protocol to maintain information about active iSCSI devices on the network, including their IP addresses, iSCSI node names (IQNs), and portal groups.

The iSNS protocol enables automated discovery and management of iSCSI devices on an IP storage network. An iSCSI initiator can query the iSNS server to discover iSCSI target devices.

NetApp does not supply or resell iSNS servers. You can obtain these servers from a vendor supported by NetApp.

How SVMs interact with an iSNS server

The iSNS server communicates with each storage virtual machine (SVM) through the SVM management LIF. The management LIF registers all iSCSI target node name, alias, and portal information with the iSNS service for a specific SVM.

In the following example, SVM VS1 uses the SVM management LIF `vs1_mgmt_lif` to register with the iSNS server. During iSNS registration, an SVM sends all the iSCSI LIFs through the SVM management LIF to the iSNS Server. After the iSNS registration is complete, the iSNS server has a list of all the LIFs serving iSCSI in VS1. If a cluster contains multiple SVMs, each SVM must register individually with the iSNS server to use the iSNS service.

In the next example, after the iSNS server completes the registration with the target, Host A can discover all the LIFs for VS1 through the iSNS server as indicated in step 1. After Host A completes the discovery of the LIFs for VS1, Host A can establish a connection with any of the LIFs in VS1 as shown in step 2. Host A is not aware of any of the LIFs in VS2 until the management LIF VS2_mgmt_LIF for VS2 registers with the iSNS server.

However, if you define the interface access lists, the host can only use the defined LIFs in the interface access list to access the target.

After iSNS is initially configured, ONTAP automatically updates the iSNS server when the SVM configuration settings change.

A delay of a few minutes can occur between the time you make the configuration changes and when ONTAP sends the update to the iSNS server. Force an immediate update of the iSNS information on the iSNS server:

```
vserver iscsi isns update
```

Commands for managing iSNS

ONTAP provides commands to manage your iSNS service.

If you want to...	Use this command...
Configure an iSNS service	vserver iscsi isns create
Start an iSNS service	vserver iscsi isns start
Modify an iSNS service	vserver iscsi isns modify
Display iSNS service configuration	vserver iscsi isns show
Force an update of registered iSNS information	vserver iscsi isns update

If you want to...	Use this command...
Stop an iSNS service	vserver iscsi isns stop
Remove an iSNS service	vserver iscsi isns delete
View the man page for a command	man <i>command name</i>

See the man page for each command for more information.

SAN provisioning with FC

You should be aware of the important concepts that are required to understand how ONTAP implements an FC SAN.

How FC target nodes connect to the network

Storage systems and hosts have adapters so that they can be connected to FC switches with cables.

When a node is connected to the FC SAN, each SVM registers the World Wide Port Name (WWPN) of its LIF with the switch Fabric Name Service. The WWNN of the SVM and the WWPN of each LIF is automatically assigned by ONTAP..

 Direct-connection to nodes from hosts with FC is not supported, NPIV is required and this requires a switch to be used. With iSCSI sessions, communication works with connections that are either network routed or direct-connect. However, both of these methods are supported with ONTAP.

How FC nodes are identified

Each SVM configured with FC is identified by a worldwide node name (WWNN).

How WWPNs are used

WWPNs identify each LIF in an SVM configured to support FC. These LIFs utilize the physical FC ports in each node in the cluster, which can be FC target cards, UTA or UTA2 configured as FC or FCoE in the nodes.

- Creating an initiator group

The WWPNs of the host's HBAs are used to create an initiator group (igroup). An igroup is used to control host access to specific LUNs. You can create an igroup by specifying a collection of WWPNs of initiators in an FC network. When you map a LUN on a storage system to an igroup, you can grant all the initiators in that group access to that LUN. If a host's WWPN is not in an igroup that is mapped to a LUN, that host does not have access to the LUN. This means that the LUNs do not appear as disks on that host.

You can also create port sets to make a LUN visible only on specific target ports. A port set consists of a group of FC target ports. You can bind an igroup to a port set. Any host in the igroup can access the LUNs only by connecting to the target ports in the port set.

- Uniquely identifying FC LIFs

WWPNs uniquely identify each FC logical interface. The host operating system uses the combination of the

WWNN and WWPN to identify SVMs and FC LIFs. Some operating systems require persistent binding to ensure that the LUN appears at the same target ID on the host.

How worldwide name assignments work

Worldwide names are created sequentially in ONTAP. However, because of the way ONTAP assigns them, they might appear to be assigned in a non-sequential order.

Each adapter has a pre-configured WWPN and WWNN, but ONTAP does not use these pre-configured values. Instead, ONTAP assigns its own WWPNs or WWNNs, based on the MAC addresses of the onboard Ethernet ports.

The worldwide names might appear to be non-sequential when assigned for the following reasons:

- Worldwide names are assigned across all the nodes and storage virtual machines (SVMs) in the cluster.
- Freed worldwide names are recycled and added back to the pool of available names.

How FC switches are identified

Fibre Channel switches have one worldwide node name (WWNN) for the device itself, and one worldwide port name (WWPN) for each of its ports.

For example, the following diagram shows how the WWPNs are assigned to each of the ports on a 16-port Brocade switch. For details about how the ports are numbered for a particular switch, see the vendor-supplied documentation for that switch.

Port **0**, WWPN 20:**00**:00:60:69:51:06:b4

Port **1**, WWPN 20:**01**:00:60:69:51:06:b4

Port **14**, WWPN 20:**0e**:00:60:69:51:06:b4

Port **15**, WWPN 20:**0f**:00:60:69:51:06:b4

SAN provisioning with NVMe

Beginning with ONTAP 9.4, NVMe/FC is supported in SAN environment. NVMe/FC enables storage administrators to provision namespaces and subsystems and then map the namespaces to subsystems, similar to the way LUNs are provisioned and mapped to igroups for FC and iSCSI.

An NVMe namespace is a quantity of non-volatile memory that can be formatted into logical blocks. Namespaces are the equivalent of LUNs for FC and iSCSI protocols, and an NVMe subsystem is analogous to an igroup. An NVMe subsystem can be associated with initiators so that namespaces within the subsystem can be accessed by the associated initiators.

Although analogous in function, NVMe namespaces do not support all features supported by LUNs.

Beginning with ONTAP 9.5 a license is required to support host-facing data access with NVMe. If NVMe is enabled in ONTAP 9.4, a 90 day grace period is given to acquire the license after upgrading to ONTAP 9.5. You can enable the license using the following command:

```
system license add -license-code NVMe_license_key
```

About SAN volumes

About SAN volumes overview

ONTAP provides three basic volume provisioning options: thick provisioning, thin provisioning, and semi-thick provisioning. Each option uses different ways to manage the volume space and the space requirements for ONTAP block sharing technologies. Understanding how the options work enables you to choose the best option for your environment.

Putting SAN LUNs and NAS shares in the same FlexVol volume is not recommended. You should provision separate FlexVol volumes specifically for your SAN LUNs and you should provision separate FlexVol volumes specifically to your NAS shares. This simplifies management and replication deployments and parallels the way FlexVol volumes are supported in Active IQ Unified Manager (formerly OnCommand Unified Manager).

Thin provisioning for volumes

When a thinly provisioned volume is created, ONTAP does not reserve any extra space when the volume is created. As data is written to the volume, the volume requests the storage it needs from the aggregate to accommodate the write operation. Using thin-provisioned volumes enables you to overcommit your aggregate, which introduces the possibility of the volume not being able to secure the space it needs when the aggregate runs out of free space.

You create a thin-provisioned FlexVol volume by setting its `-space-guarantee` option to `none`.

Thick provisioning for volumes

When a thick-provisioned volume is created, ONTAP sets aside enough storage from the aggregate to ensure that any block in the volume can be written to at any time. When you configure a volume to use thick provisioning, you can employ any of the ONTAP storage efficiency capabilities, such as compression and deduplication, to offset the larger upfront storage requirements.

You create a thick-provisioned FlexVol volume by setting its `-space-slo` (service level objective) option to `thick`.

Semi-thick provisioning for volumes

When a volume using semi-thick provisioning is created, ONTAP sets aside storage space from the aggregate to account for the volume size. If the volume is running out of free space because blocks are in use by block-

sharing technologies, ONTAP makes an effort to delete protection data objects (Snapshot copies and FlexClone files and LUNs) to free up the space they are holding. As long as ONTAP can delete the protection data objects fast enough to keep pace with the space required for overwrites, the write operations continue to succeed. This is called a “best effort” write guarantee.

Note: The following functionality is not supported on volumes that use semi-thick provisioning:

- storage efficiency technologies such as deduplication, compression, and compaction
- Microsoft Offloaded Data Transfer (ODX)

You create a semi-thick-provisioned FlexVol volume by setting its `-space-slo` (service level objective) option to `semi-thick`.

Use with space-reserved files and LUNs

A space-reserved file or LUN is one for which storage is allocated when it is created. Historically, NetApp has used the term “thin-provisioned LUN” to mean a LUN for which space reservation is disabled (a non-space-reserved LUN).

Note: Non-space-reserved files are not generally referred to as “thin-provisioned files”.

The following table summarizes the major differences in how the three volume provisioning options can be used with space-reserved files and LUNs:

Volume provisioning	LUN/file space reservation	Overwrites	Protection data ²	Storage efficiency ³
Thick	Supported	Guaranteed ¹	Guaranteed	Supported
Thin	No effect	None	Guaranteed	Supported
Semi-thick	Supported	Best effort ¹	Best effort	Not supported

Notes

1. The ability to guarantee overwrites or provide a best-effort overwrite assurance requires that space reservation is enabled on the LUN or file.
2. Protection data includes Snapshot copies, and FlexClone files and LUNs marked for automatic deletion (backup clones).
3. Storage efficiency includes deduplication, compression, any FlexClone files and LUNs not marked for automatic deletion (active clones), and FlexClone subfiles (used for Copy Offload).

Support for SCSI thin-provisioned LUNs

ONTAP supports T10 SCSI thin-provisioned LUNs as well as NetApp thin-provisioned LUNs. T10 SCSI thin provisioning enables host applications to support SCSI features including LUN space reclamation and LUN space monitoring capabilities for blocks environments. T10 SCSI thin provisioning must be supported by your SCSI host software.

You use the ONTAP `space-allocation` setting to enable/disable support for the T10 thin provisioning on a LUN. You use the ONTAP `space-allocation enable` setting to enable T10 SCSI thin provisioning on a LUN.

The [-space-allocation {enabled|disabled}] command in the ONTAP Command Reference Manual has more information to enable/disable support for the T10 thin provisioning and to enable T10 SCSI thin provisioning on a LUN.

ONTAP 9 commands

Configure volume provisioning options

You can configure a volume for thin provisioning, thick provisioning, or semi-thick provisioning.

About this task

Setting the -space-slo option to thick ensures the following:

- The entire volume is preallocated in the aggregate. You cannot use the `volume create` or `volume modify` command to configure the volume's -space-guarantee option.
- 100% of the space required for overwrites is reserved. You cannot use the `volume modify` command to configure the volume's -fractional-reserve option

Setting the -space-slo option to semi-thick ensures the following:

- The entire volume is preallocated in the aggregate. You cannot use the `volume create` or `volume modify` command to configure the volume's -space-guarantee option.
- No space is reserved for overwrites. You can use the `volume modify` command to configure the volume's -fractional-reserve option.
- Automatic deletion of Snapshot copies is enabled.

Step

1. Configure volume provisioning options:

```
volume create -vserver vserver_name -volume volume_name -aggregate
aggregate_name -space-slo none|thick|semi-thick -space-guarantee none|volume
```

The -space-guarantee option defaults to none for AFF systems and for non-AFF DP volumes. Otherwise, it defaults to volume. For existing FlexVol volumes, use the `volume modify` command to configure provisioning options.

The following command configures vol1 on SVM vs1 for thin provisioning:

```
cluster1::> volume create -vserver vs1 -volume vol1 -space-guarantee
none
```

The following command configures vol1 on SVM vs1 for thick provisioning:

```
cluster1::> volume create -vserver vs1 -volume vol1 -space-slo thick
```

The following command configures vol1 on SVM vs1 for semi-thick provisioning:

```
cluster1::> volume create -vserver vs1 -volume vol1 -space-slo semi-thick
```

SAN volume configuration options

You must set various options on the volume containing your LUN. The way you set the volume options determines the amount of space available to LUNs in the volume.

Autogrow

You can enable or disable Autogrow. If you enable it, autogrow allows ONTAP to automatically increase the size of the volume up to a maximum size that you predetermine. There must be space available in the containing aggregate to support the automatic growth of the volume. Therefore, if you enable autogrow, you must monitor the free space in the containing aggregate and add more when needed.

Autogrow cannot be triggered to support Snapshot creation. If you attempt to create a Snapshot copy and there is insufficient space on the volume, the Snapshot creation fails, even with autogrow enabled.

If autogrow is disabled, the size of your volume will remain the same.

Autoshrink

You can enable or disable Autoshrink. If you enable it, autoshrink allows ONTAP to automatically decrease the overall size of a volume when the amount of space consumed in the volume decreases a predetermined threshold. This increases storage efficiency by triggering volumes to automatically release unused free space.

Snapshot autodelete

Snapshot autodelete automatically deletes Snapshot copies when one of the following occurs:

- The volume is nearly full.
- The Snapshot reserve space is nearly full.
- The overwrite reserve space is full.

You can configure Snapshot autodelete to delete Snapshot copies from oldest to newest or from newest to oldest. Snapshot autodelete does not delete Snapshot copies that are linked to Snapshot copies in cloned volumes or LUNs.

If your volume needs additional space and you have enabled both autogrow and Snapshot autodelete, by default, ONTAP attempts to acquire the needed space by triggering autogrow first. If enough space is not acquired through autogrow, then Snapshot autodelete is triggered.

Snapshot reserve

Snapshot reserve defines the amount of space in the volume reserved for Snapshot copies. Space allocated to Snapshot reserve cannot be used for any other purpose. If all of the space allocated for Snapshot reserve is used, then Snapshot copies begin to consume additional space on the volume.

Requirement for moving volumes in SAN environments

Before you move a volume that contains LUNs or namespaces, you must meet certain requirements.

- For volumes containing one or more LUNs, you should have a minimum of two paths per LUN (LIFs) connecting to each node in the cluster.

This eliminates single points of failure and enables the system to survive component failures.

- For volumes containing namespaces, the cluster must be running ONTAP 9.6 or later.

Volume move is not supported for NVMe configurations running ONTAP 9.5.

Considerations for setting fractional reserve

Fractional reserve, also called *LUN overwrite reserve*, enables you to turn off overwrite reserve for space-reserved LUNs and files in a FlexVol volume. This can help you maximize your storage utilization, but if your environment is negatively affected by write operations failing due to lack of space, you must understand the requirements that this configuration imposes.

The fractional reserve setting is expressed as a percentage; the only valid values are 0 and 100 percent. The fractional reserve setting is an attribute of the volume.

Setting fractional reserve to 0 increases your storage utilization. However, an application accessing data residing in the volume could experience a data outage if the volume is out of free space, even with the volume guarantee set to `volume`. With proper volume configuration and use, however, you can minimize the chance of writes failing. ONTAP provides a “best effort” write guarantee for volumes with fractional reserve set to 0 when *all* of the following requirements are met:

- Deduplication is not in use
- Compression is not in use
- FlexClone sub-files are not in use
- All FlexClone files and FlexClone LUNs are enabled for automatic deletion

This is not the default setting. You must explicitly enable automatic deletion, either at creation time or by modifying the FlexClone file or FlexClone LUN after it is created.

- ODX and FlexClone copy offload are not in use
- Volume guarantee is set to `volume`
- File or LUN space reservation is enabled
- Volume Snapshot reserve is set to 0
- Volume Snapshot copy automatic deletion is enabled with a commitment level of `destroy`, a destroy list of `lun_clone, vol_clone, cifs_share, file_clone, sfsr`, and a trigger of `volume`

This setting also ensures that FlexClone files and FlexClone LUNs are deleted when necessary.

Note that if your rate of change is high, in rare cases the Snapshot copy automatic deletion could fall behind,

resulting in the volume running out of space, even with all of the above required configuration settings in use.

In addition, you can optionally use the volume autogrow capability to decrease the likelihood of volume Snapshot copies needing to be deleted automatically. If you enable the autogrow capability, you must monitor the free space in the associated aggregate. If the aggregate becomes full enough that the volume is prevented from growing, more Snapshot copies will probably be deleted as the free space in the volume is depleted.

If you cannot meet all of the above configuration requirements and you need to ensure that the volume does not run out of space, you must set the volume's fractional reserve setting to 100. This requires more free space up front, but guarantees that data modification operations will succeed even when the technologies listed above are in use.

The default value and allowed values for the fractional reserve setting depend on the guarantee of the volume:

Volume guarantee	Default fractional reserve	Allowed values
Volume	100	0, 100
None	0	0, 100

About host-side space management

Host-side space management overview

In a thinly provisioned environment, host side space management completes the process of managing space from the storage system that has been freed in the host file system.

A host file system contains metadata to keep track of which blocks are available to store new data and which blocks contain valid data that must not be overwritten. This metadata is stored within the LUN. When a file is deleted in the host file system, the file system metadata is updated to mark that file's blocks as free space. Total file system free space is then recalculated to include the newly freed blocks. To the storage system, these metadata updates appear no different from any other writes being performed by the host. Therefore, the storage system is unaware that any deletions have occurred.

This creates a discrepancy between the amount of free space reported by the host and the amount of free space reported by the underlying storage system. For example, suppose you have a newly provisioned 200-GB LUN assigned to your host by your storage system. Both the host and the storage system report 200 GB of free space. Your host then writes 100 GB of data. At this point, both the host and storage system report 100 GB of used space and 100 GB of unused space.

Then you delete 50 GB of data from your host. At this point, your host will report 50 GB of used space and 150 GB of unused space. However, your storage system will report 100 GB of used space and 100 GB of unused space.

Host-side space management uses various methods to reconcile the space differential between the host and the storage system.

Automatic host-side space management with SCSI thinly provisioned LUNs

If your host supports SCSI thin provisioning, you can enable the space-allocation option in ONTAP to turn on automatic host-side space management.

Enabling SCSI thin provisioning enables you to do the following.

- Automatic host-side space management

When data is deleted on a host that supports SCSI thin provisioning, host-side space management identifies the blocks of deleted data on the host file system and automatically issues one or more SCSI UNMAP commands to free corresponding blocks on the storage system.

- Notify the host when a LUN runs out of space while keeping the LUN online

On hosts that do not support SCSI thin provisioning, when the volume containing LUN runs out of space and cannot automatically grow, ONTAP takes the LUN offline. However, on hosts that support SCSI thin provisioning, ONTAP does not take the LUN offline when it runs out of space. The LUN remains online in read-only mode and the host is notified that the LUN can no longer accept writes.

Related information

[ONTAP SAN host configuration](#)

Enable space allocation for SCSI thinly provisioned LUNs

If you set the space-allocation option to enabled, ONTAP notifies the host when the volume has run out of space and the LUN in the volume cannot accept writes. This option also enables ONTAP to reclaim space automatically when your host deletes data.

About this task

The space-allocation option is set to disabled by default, and you must take the LUN offline to enable space allocation. After you enable space allocation, you must perform discovery on the host before the host will recognize that space allocation has been enabled.

Steps

1. Take the LUN offline.

```
lun modify -vserver vserver_name -volume volume_name -lun lun_name -state
offline
```

2. Set the -space-allocation parameter to enabled:

```
lun modify -vserver vserver_name -volume volume_name -lun lun_name -space
-allocation enabled
```

3. Verify that space allocation is enabled:

```
lun show -vserver vserver_name -volume volume_name -lun lun_name -fields
space-allocation
```

4. Bring the LUN online:

```
lun modify -vserver vserver_name -volume volume_name -lun lun_name -state
online
```

5. On the host, rescan all disks to ensure that the change to the -space-allocation option is correctly discovered.

Host support for SCSI thin provisioning

To leverage the benefits of SCSI thin provisioning, it must be supported by your host. SCSI thin provisioning uses the Logical Block Provisioning feature as defined in the SCSI SBC-3 standard. Only hosts that support this standard can use SCSI thin provisioning in ONTAP.

The following hosts currently support SCSI thin provisioning when you enable space allocation:

- VMware ESX 5.0 and later
- Red Hat Enterprise Linux 6.2 and later
- Citrix XenServer 6.5 and later
- Microsoft Windows 2012
- Microsoft Windows 2016

When you enable the space allocation functionality in ONTAP, you turn on the following SCSI thin provisioning features:

- Unmapping and reporting space usage for space reclamation
- Reporting resource exhaustion errors

Simplified host management with SnapCenter

You can use SnapCenter software to simplify some of the management and data protection tasks associated with iSCSI and FC storage. SnapCenter is an optional management package for Windows and UNIX hosts.

You can use SnapCenter Software to easily create virtual disks from pools of storage that can be distributed among several storage systems and to automate storage provisioning tasks and simplify the process of creating Snapshot copies and clones from Snapshot copies consistent with host data.

See NetApp product documentation for more information on [SnapCenter](#).

About igroups

Initiator groups (igroups) are tables of FC protocol host WWPNs or iSCSI host node names. You can define igroups and map them to LUNs to control which initiators have access to LUNs.

Typically, you want all of the host's initiator ports or software initiators to have access to a LUN. If you are using multipathing software or have clustered hosts, each initiator port or software initiator of each clustered host needs redundant paths to the same LUN.

You can create igroups that specify which initiators have access to the LUNs either before or after you create LUNs, but you must create igroups before you can map a LUN to an igroup.

Initiator groups can have multiple initiators, and multiple igroups can have the same initiator. However, you cannot map a LUN to multiple igroups that have the same initiator. An initiator cannot be a member of igroups of differing ostypes.

Example of how igroups give LUN access

You can create multiple igroups to define which LUNs are available to your hosts. For example, if you have a host cluster, you can use igroups to ensure that specific LUNs are visible to only one host in the cluster or to all of the hosts in the cluster.

The following table illustrates how four igroups give access to the LUNs for four different hosts that are accessing the storage system. The clustered hosts (Host3 and Host4) are both members of the same igroup (group3) and can access the LUNs mapped to this igroup. The igroup named group4 contains the WWPNs of Host4 to store local information that is not intended to be seen by its partner.

Hosts with HBA WWPNs, IQNs, or EUIs	igroups	WWPNs, IQNs, EUIs added to igroups	LUNs mapped to igroups
Host1, single-path (iSCSI software initiator) iqn.1991-05.com.microsoft:host1	group1	iqn.1991-05.com.microsoft:host1	/vol/vol2/lun1
Host2, multipath (two HBAs) 10:00:00:00:c9:2b:6b:3c 10:00:00:00:c9:2b:02:3c	group2	10:00:00:00:c9:2b:6b:3c 10:00:00:00:c9:2b:02:3c	/vol/vol2/lun2
Host3, multipath, clustered with host 4 10:00:00:00:c9:2b:32:1b 10:00:00:00:c9:2b:41:02	group3	10:00:00:00:c9:2b:32:1b 10:00:00:00:c9:2b:41:02 10:00:00:00:c9:2b:51:2c 10:00:00:00:c9:2b:47:a2	/vol/vol2/qtree1/lun3
Host4, multipath, clustered (not visible to Host3) 10:00:00:00:c9:2b:51:2c 10:00:00:00:c9:2b:47:a2	group4	10:00:00:00:c9:2b:51:2c 10:00:00:00:c9:2b:47:a2	/vol/vol2/qtree2/lun4 /vol/vol2/qtree1/lun5

Specify initiator WWPNs and iSCSI node names for an igroup

You can specify the iSCSI node names and WWPNs of the initiators when you create an igroup or you can add them later. If you choose to specify the initiator iSCSI node names and WWPNs when you create the LUN, they can be removed later, if needed.

Follow the instructions in your Host Utilities documentation to obtain WWPNs and to find the iSCSI node names associated with a specific host. For hosts running ESX software, use Virtual Storage Console.

Storage virtualization with VMware and Microsoft copy offload

Storage virtualization with VMware and Microsoft copy offload overview

VMware and Microsoft support copy offload operations to increase performance and network throughput. You must configure your system to meet the requirements of the VMware and Windows operating system environments to use their respective copy offload functions.

When using VMware and Microsoft copy offload in virtualized environments, your LUNs must be aligned. Unaligned LUNs can degrade performance.

Advantages of using a virtualized SAN environment

Creating a virtualized environment by using storage virtual machines (SVMs) and LIFs enables you to expand your SAN environment to all of the nodes in your cluster.

- Distributed management

You can log in to any node in the SVM to administer all of the nodes in a cluster.

- Increased data access

With MPIO and ALUA, you have access to your data through any active iSCSI or FC LIFs for the SVM.

- Controlled LUN access

If you use SLM and portsets, you can limit which LIFs an initiator can use to access LUNs.

How LUN access works in a virtualized environment

In a virtualized environment, LIFs enable hosts (clients) to access LUNs through optimized and unoptimized paths.

A LIF is a logical interface that connects the SVM to a physical port. Although multiple SVMs can have multiple LIFs on the same port, a LIF belongs to one SVM. You can access LUNs through the SVMs LIFs.

Example of LUN access with a single SVM in a cluster

In the following example, Host 1 connects to LIF1.1 and LIF1.2 in SVM-1 to access LUN1. LIF1.1 uses the physical port node1:0c and LIF1.2 uses the node2:0c. LIF1.1 and LIF1.2 belongs only to SVM-1. If a new LUN is created on node 1 or node 2, for SVM-1, then it can use these same LIFs. If a new SVM is created, then new LIFs can be created using physical ports 0c or 0d on both the nodes.

Example of LUN access with multiple SVMs in a cluster

A physical port can support multiple LIFs serving different SVMs. Because LIFs are associated with a particular SVM, the cluster nodes can send the incoming data traffic to the correct SVM. In the following example, each node from 1 through 4 has a LIF for SVM-2 using the physical port 0c on each node. Host 1 connects to LIF1.1 and LIF1.2 in SVM-1 to access LUN1. Host 2 connects to LIF2.1 and LIF2.2 in SVM-2 to access LUN2. Both SVMs are sharing the physical port 0c on the nodes 1 and 2. SVM-2 has additional LIFs that Host 2 is using to access LUNs 3 and 4. These LIFs are using physical port 0c on nodes 3 and 4. Multiple SVMs can share the physical ports on the nodes.

Example of an active or optimized path to a LUN from a host system

In an active or optimized path, the data traffic does not travel over the cluster network; it travels the most direct route to the LUN. The active or optimized path to LUN1 is through LIF1.1 in node1, using physical port 0c. Host 2 has two active or optimized paths, one path to node1, LIF2.1, which is sharing physical port 0c and the other path to node4, LIF2.4, which is using physical port 0c.

Example of an active or unoptimized path (indirect) path to a LUN from a host system

In an active or unoptimized path (indirect) path, the data traffic travels over the cluster network. This issue occurs only if all the active or optimized paths from a host are unavailable to handle traffic. If the path from Host 2 to SVM-2 LIF2.4 is lost, then access to LUN3 and LUN4 traverses the cluster network. Access from Host 2 uses LIF2.3 on node3. Then the traffic enters the cluster network switch and backs up to node4 for access to the LUN3 and LUN4. It will then traverse back over the cluster network switch and then back out through LIF2.3 to Host 2. This active or unoptimized path is used until the path to LIF2.4 is restored or a new LIF is established for SVM-2 on another physical port on node 4.

Considerations for LIFs in cluster SAN environments

You must be aware of certain LIF considerations in a SAN environment.

- Initiators must use Multipath I/O (MPIO) and asymmetric logical unit access(ALUA) for failover capability for clusters in a SAN iSCSI or FC environment because SAN does not support automatic failover for LIFs.
- At least one SAN LIF of the appropriate protocol must be configured on each node that hosts a mapped LUN and the node's HA partner.

You can configure two LIFs per node, one for each fabric being used with FC and to separate Ethernet networks for iSCSI.

- Some options are not applicable for iSCSI or FC.

For example, you cannot use IP addresses with FC.

Improve VMware VAAI performance for ESX hosts

ONTAP supports certain VMware vStorage APIs for Array Integration (VAAI) features when the ESX host is running ESX 4.1 or later. These features help offload operations from the ESX host to the storage system and increase the network throughput. The ESX host enables the features automatically in the correct environment.

The VAAI feature supports the following SCSI commands:

- EXTENDED_COPY

This feature enables the host to initiate the transfer of data between the LUNs or within a LUN without involving the host in the data transfer. This results in saving ESX CPU cycles and increasing the network throughput. The extended copy feature, also known as "copy offload," is used in scenarios such as cloning a virtual machine. When invoked by the ESX host, the copy offload feature copies the data within the storage system rather than going through the host network. Copy offload transfers data in the following ways:

- Within a LUN
 - Between LUNs within a volume
 - Between LUNs on different volumes within a storage virtual machine (SVM)
 - Between LUNs on different SVMs within a cluster
- If this feature cannot be invoked, the ESX host automatically uses the standard READ and WRITE commands for the copy operation.

- WRITE_SAME

This feature offloads the work of writing a repeated pattern, such as all zeros, to a storage array. The ESX host uses this feature in operations such as zero-filling a file.

- COMPARE_AND_WRITE

This feature bypasses certain file access concurrency limits, which speeds up operations such as booting up virtual machines.

Requirements for using the VAAI environment

The VAAI features are part of the ESX operating system and are automatically invoked by the ESX host when you have set up the correct environment.

The environment requirements are as follows:

- The ESX host must be running ESX 4.1 or later.
- The NetApp storage system that is hosting the VMware datastore must be running ONTAP.
- (Copy offload only) The source and the destination of the VMware copy operation must be hosted on the same storage system within the same cluster.

The copy offload feature currently does not support copying data between VMware datastores that are hosted on different storage systems.

Determine if VAAI features are supported by ESX

To confirm whether the ESX operating system supports the VAAI features, you can check the vSphere Client or use any other means of accessing the host. ONTAP supports the SCSI commands by default.

You can check your ESX host advanced settings to determine whether VAAI features are enabled. The table indicates which SCSI commands correspond to ESX control names.

SCSI command	ESX control name (VAAI feature)
EXTENDED_COPY	HardwareAcceleratedMove
WRITE_SAME	HardwareAcceleratedInit
COMPARE_AND_WRITE	HardwareAcceleratedLocking

Microsoft Offloaded Data Transfer (ODX)

Microsoft Offloaded Data Transfer (ODX) overview

Microsoft Offloaded Data Transfer (ODX), also known as *copy offload*, enables direct data transfers within a storage device or between compatible storage devices without transferring the data through the host computer.

ONTAP supports ODX for both the SMB and SAN protocols.

In non-ODX file transfers, the data is read from the source and is transferred across the network to the host. The host transfers the data back over the network to the destination. In ODX file transfer, the data is copied directly from the source to the destination without passing through the host.

Because ODX offloaded copies are performed directly between the source and destination, significant performance benefits are realized, including faster copy time, reduced utilization of CPU and memory on the client, and reduced network I/O bandwidth utilization.

For SAN environments, ODX is only available when it is supported by both the host and the storage system. Client computers that support ODX and have ODX enabled automatically and transparently use offloaded file transfer when moving or copying files. ODX is used regardless of whether you drag-and-drop files through Windows Explorer or use command-line file copy commands, or whether a client application initiates file copy requests.

Requirements for using ODX

If you plan to use ODX for copy offloads, you need to be familiar with volume support considerations, system requirements, and software capability requirements.

To use ODX, your system must have the following:

- ONTAP

ODX is automatically enabled in supported versions of ONTAP.

- Minimum source volume of 2 GB

For optimal performance, the source volume should be greater than 260 GB.

- Deduplication

ODX uses deduplication as part of the copy process. If you do not want deduplication on your SVM, you should disable ODX on that SVM.

- ODX support on the Windows client

ODX is supported in Windows Server 2012 or later and in Windows 8 or later. The Interoperability Matrix contains the latest information about supported Windows clients.

[NetApp Interoperability Matrix Tool](#)

- Copy application support for ODX

The application that performs the data transfer must support ODX. Application operations that support ODX include the following:

- Hyper-V management operations, such as creating and converting virtual hard disks (VHDs), managing Snapshot copies, and copying files between virtual machines
- Windows Explorer operations
- Windows PowerShell copy commands
- Windows command prompt copy commands

The Microsoft TechNet Library contains more information about supported ODX applications on Windows servers and clients.

- If you use compressed volumes, the compression group size must be 8K.

32K compression group size is not supported.

ODX does not work with the following volume types:

- Source volumes with capacities of less than 2 GB
- Read-only volumes
- [FlexCache volumes](#)
- [Semi-thick provisioned volumes](#)

Use cases for ODX

You should be aware of the use cases for using ODX on SVMs so that you can determine under what circumstances ODX provides you with performance benefits.

Windows servers and clients that support ODX use copy offload as the default way of copying data across remote servers. If the Windows server or client does not support ODX or the ODX copy offload fails at any point, the copy or move operation falls back to traditional reads and writes for the copy or move operation.

The following use cases support using ODX copies and moves:

- Intra-volume

The source and destination files or LUNs are within the same volume.

- Inter-volume, same node, same SVM

The source and destination files or LUNs are on different volumes that are located on the same node. The data is owned by the same SVM.

- Inter-volume, different nodes, same SVM

The source and destination files or LUNs are on different volumes that are located on different nodes. The data is owned by the same SVM.

- Inter-SVM, same node

The source and destination file or LUNs are on different volumes that are located on the same node. The data is owned by different SVMs.

- Inter-SVM, different nodes

The source and destination file or LUNs are on different volumes that are located on different nodes. The data is owned by different SVMs.

- Inter-cluster

The source and destination LUNs are on different volumes that are located on different nodes across clusters. This is only supported for SAN and does not work for SMB.

There are some additional special use cases:

- With the ONTAP ODX implementation, you can use ODX to copy files between SMB shares and FC or iSCSI attached virtual drives.

You can use Windows Explorer, the Windows CLI or PowerShell, Hyper-V, or other applications that support ODX to copy or move files seamlessly using ODX copy offload between SMB shares and connected LUNs, provided that the SMB shares and LUNs are on the same cluster.

- Hyper-V provides some additional use cases for ODX copy offload:

- You can use ODX copy offload pass-through with Hyper-V to copy data within or across virtual hard disk (VHD) files or to copy data between mapped SMB shares and connected iSCSI LUNs within the same cluster.

This allows copies from guest operating systems to pass through to the underlying storage.

- When creating fixed-sized VHDs, ODX is used for initializing the disk with zeros, using a well-known zeroed token.
- ODX copy offload is used for virtual machine storage migration if the source and destination storage is on the same cluster.

To take advantage of the use cases for ODX copy offload pass-through with Hyper-V, the guest operating system must support ODX and the guest operating system's disks must be SCSI disks backed by storage (either SMB or SAN) that supports ODX. IDE disks on the guest operating system do not support ODX pass-through.

Special system file requirements

You can delete ODX files found in qtrees. You must not remove or modify any other ODX system files unless you are told by technical support to do so.

When using the ODX feature, there are ODX system files that exist in every volume of the system. These files enable point-in-time representation of data used during the ODX transfer. The following system files are in the root level of each volume that contains LUNs or files to which data was offloaded:

- .copy-offload (a hidden directory)
- .tokens (file under the hidden .copy-offload directory)

You can use the `copy-offload delete-tokens -path dir_path -node node_name` command to delete a qtree containing an ODX file.

SAN configuration reference

SAN configuration reference

The following sections describe supported FC-NVMe, FC, iSCSI, and FCoE topologies for connecting host computers to nodes, and list supported limits for SAN components.

You should use this information in conjunction with basic SAN configuration documentation:

- [SAN administration overview](#)

Considerations for iSCSI configurations

Considerations for iSCSI configurations overview

You should consider several things when setting up your iSCSI configuration.

- You can set up your iSCSI configuration with single nodes or with HA pairs.

Direct connect or the use of Ethernet switches is supported for connectivity. You must create LIFs for both types of connectivity

- You should configure one management LIF for every storage virtual machine (SVM) supporting SAN.
- Selective LUN mapping (SLM) limits the paths that are being utilized in accessing the LUNs owned by an HA pair.

This is the default behavior for LUNs created with ONTAP releases.

- HA pairs are defined as the reporting nodes for the Active/Optimized and the Active/Unoptimized paths that will be used by the host in accessing the LUNs through ALUA.
- It is recommended that all SVMs in iSCSI configurations have a minimum of two LIF's per node in separate Ethernet networks for redundancy and MPIO across multiple paths.
- You need to create one or more iSCSI paths from each node in an HA pair, using logical interfaces (LIFs) to allow access to LUNs that are serviced by the HA pair.

If a node fails, LIFs do not migrate or assume the IP addresses of the failed partner node. Instead, the

MPIO software, using ALUA on the host, is responsible for selecting the appropriate paths for LUN access through LIFs.

- VLANs offer specific benefits, such as increased security and improved network reliability that you might want to leverage in iSCSI.

Ways to configure iSCSI SAN hosts with single nodes

You can configure the iSCSI SAN hosts to connect directly to a single node or by using either one or multiple IP switches. You should determine whether you want a single-switch configuration that is not completely redundant or a multi-switch configuration that is completely redundant.

You can configure iSCSI SAN hosts in a direct-attached, single-switch, or multi-switch environment. If there are multiple hosts connecting to the node, each host can be configured with a different operating system. For single and multi-network configurations, the node can have multiple iSCSI connections to the switch, but multipathing software that supports ALUA is required.

If there are multiple paths from the host to the controller, then ALUA must be enabled on the host.

Direct-attached single-node configurations

In direct-attached configurations, one or more hosts are directly connected to the node.

Single-network single-node configurations

In single-network single-node configurations, one switch connects a single node to one or more hosts. Because there is a single switch, this configuration is not fully redundant.

Multi-network single-node configurations

In multi-network single-node configurations, two or more switches connect a single node to one or more hosts. Because there are multiple switches, this configuration is fully redundant.

Ways to configure iSCSI SAN hosts with HA pairs

You can configure the iSCSI SAN hosts to connect to dual-node or multi-node configurations by using either one or multiple IP switches. You should determine whether you want a single-switch configuration that is not completely redundant or a multi-switch configuration that is completely redundant.

You can configure iSCSI SAN hosts with single controllers and HA pairs on direct-attached, single-network, or multi-network environments. HA pairs can have multiple iSCSI connections to each switch, but multipathing

software that supports ALUA is required on each host. If there are multiple hosts, you can configure each host with a different operating system by checking the NetApp Interoperability Matrix Tool.

NetApp Interoperability Matrix Tool

Direct-attachment

In a direct-attached configuration, one or more hosts are directly connected to the controllers.

Single-network HA pairs

In single-network HA pair configurations, one switch connects the HA pair to one or more hosts. Because there is a single switch, this configuration is not fully redundant.

Multi-network HA pairs

In multi-network HA pair configurations, two or more switches connect the HA pair to one or more hosts. Because there are multiple switches, this configuration is fully redundant.

Benefits of using VLANs in iSCSI configurations

A VLAN consists of a group of switch ports grouped together into a broadcast domain. A VLAN can be on a single switch or it can span multiple switch chassis. Static and dynamic VLANs enable you to increase security, isolate problems, and limit available paths within your IP network infrastructure.

When you implement VLANs in large IP network infrastructures, you derive the following benefits:

- Increased security.

VLANs enable you to leverage existing infrastructure while still providing enhanced security because they limit access between different nodes of an Ethernet network or an IP SAN.

- Improved Ethernet network and IP SAN reliability by isolating problems.
- Reduction of problem resolution time by limiting the problem space.
- Reduction of the number of available paths to a particular iSCSI target port.
- Reduction of the maximum number of paths used by a host.

Having too many paths slows reconnect times. If a host does not have a multipathing solution, you can use VLANs to allow only one path.

Dynamic VLANs

Dynamic VLANs are MAC address-based. You can define a VLAN by specifying the MAC address of the members you want to include.

Dynamic VLANs provide flexibility and do not require mapping to the physical ports where the device is physically connected to the switch. You can move a cable from one port to another without reconfiguring the VLAN.

Static VLANs

Static VLANs are port-based. The switch and switch port are used to define the VLAN and its members.

Static VLANs offer improved security because it is not possible to breach VLANs using media access control (MAC) spoofing. However, if someone has physical access to the switch, replacing a cable and reconfiguring the network address can allow access.

In some environments, it is easier to create and manage static VLANs than dynamic VLANs. This is because static VLANs require only the switch and port identifier to be specified, instead of the 48-bit MAC address. In addition, you can label switch port ranges with the VLAN identifier.

Considerations for FC-NVMe configurations

Beginning with ONTAP 9.4, the non-volatile memory express (NVMe) protocol is available for SAN environments. FC-NVMe allows you to run NVMe over an existing FC network with an AFF system. FC-NVMe uses the same physical setup and zoning practice as traditional FC networks but allows for greater bandwidth, increased IOPs and reduced latency than FC-SCSI.

Supported configurations:

- NVMe is supported on AFF platforms that have 32G FC ports.
- You can set up your FC-NVMe configuration with single nodes or HA pairs using a single fabric or multifabric.
- Beginning in ONTAP 9.11.1, NVMe is supported clusters with up to 12 nodes. Beginning in ONTAP 9.4, NVMe is supported clusters up to 4 nodes.
- NVMe can be the only data protocol on the storage virtual machine (SVM).
- Up to 8 NVMe SVMs are supported per cluster.
- FC-NVMe can be the only data protocol on data LIFs.
- LUNs and namespaces cannot be mixed on the same volume.
- You should configure one management LIF for every SVM supporting SAN.
- The use of heterogeneous FC switch fabrics is not supported, except in the case of embedded blade switches.

Specific exceptions are listed on the [NetApp Interoperability Matrix Tool](#).

- Cascade, partial mesh, full mesh, core-edge, and director fabrics are all industry-standard methods of connecting FC switches to a fabric, and all are supported.

A fabric can consist of one or multiple switches, and the storage controllers can be connected to multiple switches.

Functionality enhancements:

This functionality is supported...	Starting with...
volume move with mapped namespaces	ONTAP 9.6

Namespaces support 512 byte blocks and 4096 byte blocks. 4096 is the default value. 512 should only be used if the host operating system does not support 4096 byte blocks.	ONTAP 9.6
Multipath HA pair failover/giveback	ONTAP 9.5

The following applies only to nodes running ONTAP 9.4:

- NVMe LIFs and namespaces must be hosted on the same node.
- The NVMe service must be created before the NVMe LIF is created.

The following ONTAP features are not supported by NVMe configurations:

- NVMe namespace move
- NVMe namespaces (Copy on Demand)
- Creating namespaces on a volume transitioned from Data ONTAP operating in 7-mode.
- Sync
- Virtual Storage Console

See the [NetApp Hardware Universe](#) for a complete list of NVMe limits.

Considerations for FC configurations

Considerations for FC configurations overview

You should be aware of several things when setting up your FC configuration.

- You can set up your FC configuration with single nodes or HA pairs using a single fabric or multifabric.
- You should configure two FC data LIFs per node.

This creates redundancy and protects against loss of data access.

- You should configure one management LIF for every storage virtual machine (SVM) supporting SAN.
- Multiple hosts, using different operating systems, such as Windows, Linux, or UNIX, can access the storage solution at the same time.

Hosts require that a supported multipathing solution be installed and configured. Supported operating systems and multipathing solutions can be verified on the Interoperability Matrix.

- ONTAP supports single, dual, or multiple node solutions that are connected to multiple physically independent storage fabrics; a minimum of two are recommended for SAN solutions.

This provides redundancy at the fabric and storage system layers. Redundancy is particularly important because these layers typically support many hosts.

- The use of heterogeneous FC switch fabrics is not supported, except in the case of embedded blade switches.

Specific exceptions are listed on the Interoperability Matrix.

- Cascade, partial mesh, full mesh, core-edge, and director fabrics are all industry-standard methods of connecting FC switches to a fabric, and all are supported.

A fabric can consist of one or multiple switches, and the storage controllers can be connected to multiple switches.

Ways to configure FC and FC-NVMe SAN hosts with single nodes

You can configure FC and FC-NVMe SAN hosts with single nodes through one or more fabrics. N-Port ID Virtualization (NPIV) is required and must be enabled on all FC switches in the fabric. You cannot directly attach FC or FC-NVMe SAN hosts to single nodes without using an FC switch.

You can configure FC or FC-NVMe SAN hosts with single nodes through a single fabric or multifabrics. The FC target ports (0a, 0c, 0b, 0d) in the illustrations are examples. The actual port numbers vary depending on the model of your storage node and whether you are using expansion adapters.

Single-fabric single-node configurations

In single-fabric single-node configurations, there is one switch connecting a single node to one or more hosts. Because there is a single switch, this configuration is not fully redundant. All hardware platforms that support FC and FC-NVMe support single-fabric single-node configurations. However, the FAS2240 platform requires the X1150A-R6 expansion adapter to support a single-fabric single-node configuration.

The following figure shows a FAS2240 single-fabric single-node configuration. It shows the storage controllers side by side, which is how they are mounted in the FAS2240-2. For the FAS2240-4, the controllers are mounted one above the other. There is no difference in the SAN configuration for the two models.

Multifabric single-node configurations

In multifabric single-node configurations, there are two or more switches connecting a single node to one or more hosts. For simplicity, the following figure shows a multifabric single-node configuration with only two fabrics, but you can have two or more fabrics in any multifabric configuration. In this figure, the storage controller is mounted in the top chassis and the bottom chassis can be empty or can have an IOMX module, as it does in this example.

Related information

[NetApp Technical Report 4684: Implementing and Configuring Modern SANs with NVMe/FC](#)

Ways to configure FC & FC-NVMe SAN hosts with HA pairs

You can configure FC and FC-NVMe SAN hosts to connect to HA pairs through one or

more fabrics. You cannot directly attach FC or FC-NVMe SAN hosts to HA pairs without using a switch.

You can configure FC and FC-NVMe SAN hosts with single fabric HA pairs or with multifabric HA pairs. The FC target port numbers (0a, 0c, 0d, 1a, 1b) in the illustrations are examples. The actual port numbers vary depending on the model of your storage node and whether you are using expansion adapters.

Single-fabric HA pairs

In single-fabric HA pair configurations, there is one fabric connecting both controllers in the HA pair to one or more hosts. Because the hosts and controllers are connected through a single switch, single-fabric HA pairs are not fully redundant.

All platforms that support FC configurations support single-fabric HA pair configurations, except the FAS2240 platform. The FAS2240 platform only supports single-fabric single-node configurations.

Multifabric HA pairs

In multifabric HA pairs, there are two or more switches connecting HA pairs to one or more hosts. For simplicity, the following multifabric HA pair figure shows only two fabrics, but you can have two or more fabrics in any multifabric configuration:

FC switch configuration best practices

For best performance, you should consider certain best practices when configuring your FC switch.

A fixed link speed setting is the best practice for FC switch configurations, especially for large fabrics because it provides the best performance for fabric rebuilds and can significantly save time. Although autonegotiation provides the greatest flexibility, FC switch configuration does not always perform as expected, and it adds time to the overall fabric-build sequence.

All of the switches that are connected to the fabric must support N_Port ID virtualization (NPIV) and must have NPIV enabled. ONTAP uses NPIV to present FC targets to a fabric.

For details about which environments are supported, see the [NetApp Interoperability Matrix Tool](#).

For FC and iSCSI best practices, see [Best Practices for Scalable SAN - ONTAP 9](#).

Supported number of FC hop counts

The maximum supported FC hop count between a host and storage system depends on the switch supplier and storage system support for FC configurations.

The hop count is defined as the number of switches in the path between the initiator (host) and target (storage system). Cisco also refers to this value as the *diameter of the SAN fabric*.

Switch supplier	Supported hop count
Brocade	7 for FC5 for FCoE

Switch supplier	Supported hop count
Cisco	7 for FCUp to 3 of the switches can be FCoE switches.

Related information

[NetApp Downloads: Brocade Scalability Matrix Documents](#)

[NetApp Downloads: Cisco Scalability Matrix Documents](#)

FC target port supported speeds

FC target ports can be configured to run at different speeds. You should set the target port speed to match the speed of the device to which it connects. All target ports used by a given host should be set to the same speed.

FC target ports can be used for FC-NVMe configurations in the exact same way they are used for FC configurations.

You should set the target port speed to match the speed of the device to which it connects instead of using autonegotiation. A port that is set to autonegotiation can take longer to reconnect after a takeover/giveback or other interruption.

You can configure onboard ports and expansion adapters to run at the following speeds. Each controller and expansion adapter port can be configured individually for different speeds as needed.

4 Gb ports	8 Gb ports	16 Gb ports	32 Gb ports
<ul style="list-style-type: none"> • 4 Gb • 2 Gb • 1 Gb 	<ul style="list-style-type: none"> • 8 Gb • 4 Gb • 2 Gb 	<ul style="list-style-type: none"> • 16 Gb • 8 Gb • 4 Gb 	<ul style="list-style-type: none"> • 32 Gb • 16 Gb • 8 Gb

UTA2 ports can use an 8 Gb SFP+ adapter to support 8, 4, and 2 Gb speeds, if required.

FC Target port configuration recommendations

For best performance and highest availability, you should use the recommended FC target port configuration.

The following table shows the preferred port usage order for onboard FC and FC-NVMe target ports. For expansion adapters, the FC ports should be spread so that they do not use the same ASIC for connectivity. The preferred slot order is listed in [NetApp Hardware Universe](#) for the version of ONTAP software used by your controller.

FC-NVMe is supported on the following models:

- AFF A300

The AFF A300 onboard ports do not support FC-NVMe.

- AFF A700
- AFF A700s
- AFF A800

The FAS22xx and FAS2520 systems do not have onboard FC ports and do not support add-on adapters.

Controller	Port pairs with shared ASIC	Number of target ports: Preferred ports
FAS9000, AFF A700, AFF A700s and AFF A800	None	All data ports are on expansion adapters. See NetApp Hardware Universe for more information.
8080, 8060 and 8040	0e+0f 0g+0h	1: 0e 2: 0e, 0g 3: 0e, 0g, 0h 4: 0e, 0g, 0f, 0h
FAS8200 and AFF A300	0g+0h	1: 0g 2: 0g, 0h
8020	0c+0d	1: 0c 2: 0c, 0d
62xx	0a+0b 0c+0d	1: 0a 2: 0a, 0c 3: 0a, 0c, 0b 4: 0a, 0c, 0b, 0d
32xx	0c+0d	1: 0c 2: 0c, 0d
FAS2554, FAS2552, FAS2600 series, FAS2720, FAS2750, AFF A200 and AFF A220	0c+0d 0e+0f	1: 0c 2: 0c, 0e 3: 0c, 0e, 0d 4: 0c, 0e, 0d, 0f

Manage systems with FC adapters

Managing systems with FC adapters overview

Commands are available to manage onboard FC adapters and FC adapter cards. These commands can be used to configure the adapter mode, display adapter information, and change the speed.

Most storage systems have onboard FC adapters that can be configured as initiators or targets. You can also use FC adapter cards configured as initiators or targets. Initiators connect to back-end disk shelves, and possibly foreign storage arrays (FlexArray). Targets connect only to FC switches. Both the FC target HBA ports and the switch port speed should be set to the same value and should not be set to auto.

Commands for managing FC adapters

You can use FC commands to manage FC target adapters, FC initiator adapters, and onboard FC adapters for your storage controller. The same commands are used to manage FC adapters for the FC protocol and the FC-NVMe protocol.

FC initiator adapter commands work only at the node level. You must use the `run -node node_name` command before you can use the FC initiator adapter commands.

Commands for managing FC target adapters

If you want to...	Use this command...
Display FC adapter information on a node	<code>network fcp adapter show</code>
Modify FC target adapter parameters	<code>network fcp adapter modify</code>
Display FC protocol traffic information	<code>run -node node_name sysstat -f</code>
Display how long the FC protocol has been running	<code>run -node node_name uptime</code>
Display adapter configuration and status	<code>run -node node_name sysconfig -v adapter</code>
Verify which expansion cards are installed and whether there are any configuration errors	<code>run -node node_name sysconfig -ac</code>
View a man page for a command	<code>man command_name</code>

Commands for managing FC initiator adapters

If you want to...	Use this command...
Display information for all initiators and their adapters in a node	<code>run -node node_name storage show adapter</code>

If you want to...	Use this command...
Display adapter configuration and status	run -node <i>node_name</i> sysconfig -v adapter
Verify which expansion cards are installed and whether there are any configuration errors	run -node <i>node_name</i> sysconfig -ac

Commands for managing onboard FC adapters

If you want to...	Use this command...
Display the status of the onboard FC ports	system node hardware unified-connect show

Configure FC adapters for initiator mode

You can configure individual FC ports of onboard adapters and certain FC adapter cards for initiator mode. Initiator mode is used to connect the ports to tape drives, tape libraries, or third-party storage with FlexArray Virtualization or Foreign LUN Import (FLI).

What you'll need

- LIFs on the adapter must be removed from any port sets of which they are members.
- All LIF's from every storage virtual machine (SVM) using the physical port to be modified must be migrated or destroyed before changing the personality of the physical port from target to initiator.

About this task

Each onboard FC port can be individually configured as an initiator or a target. Ports on certain FC adapters can also be individually configured as either a target port or an initiator port, just like the onboard FC ports. A list of adapters that can be configured for target mode is available in [NetApp Hardware Universe](#).

NVMe/FC does support initiator mode.

Steps

1. Remove all LIFs from the adapter:

```
network interface delete -vserver SVM_name -lif lif_name,lif_name
```

2. Take your adapter offline:

```
network fcp adapter modify -node node_name -adapter adapter_port -status-admin down
```

If the adapter does not go offline, you can also remove the cable from the appropriate adapter port on the system.

3. Change the adapter from target to initiator:

```
system hardware unified-connect modify -t initiator adapter_port
```

4. Reboot the node hosting the adapter you changed.
5. Verify that the FC ports are configured in the correct state for your configuration:

```
system hardware unified-connect show
```

6. Bring the adapter back online:

```
node run -node node_name storage enable adapter adapter_port
```

Configure FC adapters for target mode

You can configure individual FC ports of onboard adapters and certain FC adapter cards for target mode. Target mode is used to connect the ports to FC initiators.

About this task

Each onboard FC port can be individually configured as an initiator or a target. Ports on certain FC adapters can also be individually configured as either a target port or an initiator port, just like the onboard FC ports. A list of adapters that can be configured for target mode is available in the [NetApp Hardware Universe](#).

The same steps are used when configuring FC adapters for the FC protocol and the FC-NVMe protocol. However, only certain FC adapters support FC-NVMe. See the [NetApp Hardware Universe](#) for a list of adapters that support the FC-NVMe protocol.

Steps

1. Take the adapter offline:

```
node run -node node_name storage disable adapter adapter_name
```

If the adapter does not go offline, you can also remove the cable from the appropriate adapter port on the system.

2. Change the adapter from initiator to target:

```
system node hardware unified-connect modify -t target -node node_name adapter adapter_name
```

3. Reboot the node hosting the adapter you changed.

4. Verify that the target port has the correct configuration:

```
network fcp adapter show -node node_name
```

5. Bring your adapter online:

```
network fcp adapter modify -node node_name -adapter adapter_port -state up
```

Display information about an FC target adapter

You can use the `network fcp adapter show` command to display system configuration and adapter information for any FC adapter in the system.

Step

1. Display information about the FC adapter by using the `network fcp adapter show` command.

The output displays system configuration information and adapter information for each slot that is used.

```
network fcp adapter show -instance -node node1 -adapter 0a
```

Change the FC adapter speed

You should set your adapter target port speed to match the speed of the device to which it connects, instead of using autonegotiation. A port that is set to autonegotiation can take longer time to reconnect after a takeover/giveback or other interruption.

What you'll need

All LIFs that use this adapter as their home port must be offline.

About this task

Because this task encompasses all storage virtual machines (SVMs) and all LIFs in a cluster, you must use the `-home-port` and `-home-lif` parameters to limit the scope of this operation. If you do not use these parameters, the operation applies to all LIFs in the cluster, which might not be desirable.

Steps

1. Take all of the LIFs on this adapter offline:

```
network interface modify -vserver * -lif * { -home-node node1 -home-port 0c }  
-status-admin down
```

2. Take the adapter offline:

```
